**Planetary ball mills** These are designed to comminute soft and fibrous, medium to extremely hard, and brittle materials such as ashes, bauxite, soil samples, chemicals, chamotte, fireclay, diamonds, drugs, fertilizers, enamels, earth, ores, coloring substances, rock and debris, glass, domestic and industrial waste, wood chippings, cocoa beans, sewage sludge, coal, coke, plant constituents, pigments, quartz, salts, sands, slag, silicates, cement, cement clinker, and sugar. Planetary ball mills incorporate a high-speed transmission system generating extreme centrifugal acceleration rates, thus providing for ultimate finenesses well into the submicrometer particle size range. A multitude of grinding tools made of a great variety of materials provides for the processing of trace analysis samples, often without contamination. **Figure 3E** shows four grinding stations located on a horizontally rotating platform and intercoupled to move both around their own central axes and in counter-rotation around the axis of their common platform. The resultant effect is a continuously alternating superimposition of centrifugal forces sending the grinding balls along the jar wall to traverse the jar center line and back again from the opposite

side. The dynamics involved produce a violent rebound effect in combination with high friction and impact forces, providing for excellent comminution and homogenization.

**Vibratory mixer mills** These mills comminute and homogenize soft, fibrous, hard, and brittle substances in both dry and wet conditions. They are particularly suitable for processing basalt, building material, dolomite, earth, cereals, organic tissue samples, hair, cocoa, rubber, ceramics, bones, synthetic resins, alloys, minerals, plant constituents, salts, tablets, pills, peat, and wool. **Figure 3F** shows how grinding balls comminute the sample material. The grinding cylinder, holding the sample and loaded with one or two balls, is locked in the mounting bracket and energized into horizontal, radial oscillations, thus bouncing the balls against the rounded cylinder ends so as to disintegrate the sample material. The degree of reduction and the ultimate fineness attainable are governed by the mass of the grinding balls.

**Cold grinding** The terms cold grinding, freeze grinding, or cryogenic grinding refer to comminution methods employing mechanical and thermal energies to break down solids. This method is often the only means of obtaining sufficient comminution results with acceptable homogenizing efficiency, which is particularly important when handling materials with low melting points, high grease and/or moisture contents, as well as resilient or tough consistencies.

The disintegrating behavior of substances with any such characteristics can be substantially improved by addition of carbon dioxide 'ice' or by embrittlement with liquid nitrogen. The use of direct or indirect cooling, in combination with mechanical comminution techniques, facilitates adequate processing of many types and grades of plastic, rubber, organic tissue, pharmaceutical products, spice, herbs, and food samples.

The greatest care must be taken when handling coolants, especially liquid nitrogen, and the use of protective gloves, safety goggles, etc., in keeping with the safety instructions of grinding equipment manufacturers is most important.

### General Safety Aspects

Laboratory staff are always exposed to risk when undertaking their duties, comminution procedures included. Manufacturers have made great efforts to make their equipment foolproof against handling errors: mills, for example, cannot be unloaded until the machine has come to a dead stop.

Comminution of explosive materials represents a particularly high hazard and must, therefore, be left to qualified laboratory staff with special training in this area. Included in explosion hazard is the risk of dust explosions, always likely to be present in grinding operations involving high degrees of sample comminution.

### Know the Stability of an Analyte

The purpose of this article is to discuss the importance of knowing:

- The stability of the analyte in the sample matrix.

- Any measures that can be taken to preserve the sample if the analyte is unstable.
- The importance of avoiding contamination before or during analysis.

The first stage of an analysis is sampling, where a representative sample for analysis is taken and submitted for assay; this is followed by transport to the laboratory, storage, sample preparation, and analysis. Analytical methods can be highly specific and sensitive. However, the results of an analysis are only

as good as the initial sampling and the sample preservation methods used to deliver the sample to a laboratory for analysis as well as ensuring the stability of an analyte after preparation and pending analysis.

Knowing that an analyte is stable is essential to enable an analyst to draw conclusions based upon the experimental observations. If an analyte is unstable, then steps such as the addition of preservatives or storing under known conditions can be used to stabilize an analyte. The stability of the analyte must be known from the time of sampling until analysis and calculation of final results; this overall time should include a contingency for any repeat analysis.

There are many approaches to sample preservation. For example, if the analyte shares structural similarities with another compound for which there is a proven preservation protocol, then all that may be required is a duplication of the procedure. For a novel compound, the instability problem may require a novel approach. It is important to realize that preservatives may only slow the rate of analyte degradation – they are not always a universal panacea.

Equally important during the sampling, storage, and sample preparation stages of an analysis is the need to avoid the introduction of contaminants from the environment, storage conditions, or sample container. The adsorption of the analyte onto the surface of containers can be confused with instability and complicates the sample stability and preservation problem.

Owing to the diverse nature of analytes and sample matrices, it is impossible to give specific advice about the storage and preservation under all circumstances. This must be determined on a case-by-case basis. It should be stressed that the analyst is responsible for the quality of information generated by his or her methods of analysis. Knowing the stability of the analyte from sampling through the analysis is a prime responsibility that helps ensure the quality of data generated by the analytical method.

### **General Aspects of Sampling**

There are a number of general points that set the scene for sample preservation. It begins with the assumption that the sample is homogeneous and representative of the whole from which it was derived. This is a key assumption that is covered in more detail elsewhere in this encyclopedia.

If this is not true and the sample and the bulk differ, the wrong conclusions could be drawn about the sample from the analytical results and extrapolated

to the original batch or lot of material. If the sampling site is remote from the laboratory or site of analysis, then the sample must be transported. Unless the sample results are required urgently, the sample will usually be stored at the laboratory until the analysis. In both cases, the samples will be stored prior to analysis. The storage conditions to preserve the analytes must be known and followed; otherwise the analytical results will be flawed. Sample preservation may also be required during the sample preparation stages to ensure the integrity of the analyte.

### **Sample Information**

The sampling information required by the analyst, with respect to sample preservation, are that a sampling protocol that ensures analyte preservation was followed correctly together with the history of the sample's transport and storage before receipt in the laboratory.

### **Sample Labeling**

All laboratories, including those operating under a quality scheme such as ISO 17025, Good Laboratory Practice (GLP) or Good Manufacturing Practice (GMP), must ensure that the sample is labeled correctly. It is the analysts' responsibility to ensure that this is done properly, either by themselves or by a third party who is performing the sampling. All relevant information should be gathered about the sample to aid the analyst. If the sample is from a system that changes with time, e.g., river water, then the date and time of sampling must be noted to ensure that the results have relevance to the sample, e.g., if a sample is connected with litigation over an illegal discharge into a river.

Labels must be appropriate to the conditions under which the samples will be taken and stored. It is not advisable, for example, to use labels marked with water-soluble ink if sampling river water. Equally, labels that could disintegrate with successive freeze/thaw cycles for the analysis of biological samples would be inviting disaster.

### **Sample Containers**

Containers are necessary to keep each sample discrete and are essential when the sampling site is remote from the laboratory. They should be of sufficient size and volume to ensure that they hold sufficient sample for the analysis and any repeat assays. This may not always be the case but the analyst should discuss with the submitter the minimum requirements for a particular assay.

Sample containers must be fit for the purpose to which they will be put. This has many aspects:

- They must be able to hold sufficient sample for the analysis and have sufficient sample for a repeat if required.
- They must be made of inert material that does not have any interaction with the sample such as absorption or adsorption. The containers used for sample storage must be evaluated for inertness and purity. Some containers or the stoppers can introduce phthalate plasticizer or other interfering compounds into an assay; care must be taken with the use of sample containers.
- They must be robust enough to cope with sampling, transport, and storage conditions that are likely to be encountered. The lids of any container must fit tightly to prevent any loss of sample during transportation and storage if tipped and to prevent any entry of air especially if the sample is susceptible to oxidation. Alternatively the cap must fit securely to avoid sample loss.
- Reuse of containers is a judgment based upon the analytical requirements, the information generated by the analyst, and economic factors of recycling versus purchase of disposable containers. If recycled, great care must be taken to avoid contamination by the cleaning process. This will be discussed later under contamination.

Although not normally taken into account, containers may influence the results of an assay, especially when quantifying trace amounts. To prevent the introduction of any artifacts they must be clean. The best way to determine the suitability of containers and the cleaning conditions is by experiment during method development and validation before starting work. However, there are many situations where the work starts, problems are seen and then investigated, thus wasting time and effort and potentially presenting the wrong information. Often in this context the use of disposable containers, especially for biological samples, is one way to ensure that the container is clean and avoids the need to cleanse the sample containers before reuse. Washing the containers for recycling is a process that can introduce contamination from the chemicals used; this again must be evaluated carefully before its introduction. For example, detergents containing phosphates cannot be used if phosphates or surface-active agents are being measured. In the same way, sulfuric acid cannot be used as a wash if traces of sulfate are being measured.

### Sample Transport

When transporting samples from the sampling site to the laboratory (this can encompass from laboratory

to laboratory and continent to continent) it is essential to ensure that the process does not prejudice the integrity of the sample or affect any results in any way. The analyst should investigate the transport of samples especially if movement of the sample is possible. Ideally, all samples should be transported to a laboratory as soon as possible after collection. The samples should be sealed and packaged in such a way as to avoid breakage, deterioration, or losing the contents.

Biological samples are usually frozen after sampling and transported in the same state, thus they will be solid and the major problem here will be thawing and possible analyte decomposition at ambient temperatures. Other samples may be liquid or a powder under the shipping conditions; care must be taken to ensure that movement of the sample does not break the container and careful packaging is essential to ensure safe arrival of the shipment at the laboratory.

### Sources of Analyte Loss

There are a number of processes that can cause analyte loss. Some, such as diffusion, are limited to fluid samples. Others, such as oxidation, may be applicable to many types of sample. The main processes contributing to analyte loss are discussed below. If a problem of sample stability arises, one or more of the following processes may be responsible for the loss. Therefore, the problem may require more than one solution to solve it.

- **Light** – Photodecomposition of material is a common cause of instability. Therefore, in the first instance, samples should be stored out of direct sunlight and in brown bottles. If photodecomposition is a particularly bad problem, then the samples should be kept in aluminum foil and all working solutions of the sample and the standards should be treated similarly. When measuring nifedipine in plasma, the analysis is best undertaken in yellow light to avoid photodecomposition; yellow light is suitable for the analysis of some vitamins.
- **Oxidation** – Compounds that are easily oxidized should be kept in containers that have tightly fitting lids to exclude air. If necessary, the sample container should be flushed with nitrogen or an alternative inert gas to displace all oxygen present or the container should be filled completely with the sample.
- **Temperature** – It is important to know the stability of samples awaiting analysis. This can take many forms depending on the type of sample. For instance, biological samples containing analytes must be investigated to find out the stability of analytes in

the particular matrix at ambient, refrigerated, and subzero temperatures. This situation may be most relevant to environmental samples where the compound or elemental species may undergo conversion to another form under the influence of microbial activity. A study on storage temperature will give an indication of the time that the sample can be stored before the analyte suffers degradation that renders the results useless. Samples taken at high temperatures from chemical processes may change composition upon cooling; care must be taken to ensure that the results relate to the actual material.

- **Biodegradation** – Enzymes present in the sample can hydrolyze conjugated material and release extra material for analysis or alter the analyte reducing the amount available for assay. Microbial contamination can have a similar effect and can metabolize components of the sample and produce others. This activity can affect dissolved oxygen and carbon dioxide through to nitrogenous compound and carbohydrates.

- **Preservatives** – Whatever chemical is used to preserve a sample, the effect on the overall assay must be assessed in order to prevent the introduction of another source of interference to the analytical procedure. This is especially important in trace element analysis where the preservative could introduce the very elements that are being quantified.

- **Evaporation or volatility** – Storing samples at low temperatures, in containers where there is no room for evaporation, or if the end of the container is firmly stoppered can prevent this from occurring.

- **Adsorption or absorption** – These can cause losses where the analyte is irreversibly attached on the surface of a sample container or solid particles contained in the sample. To avoid losses of this type either a container made from a different material should be tried or chemical modification of the interior surface of the container, e.g., by silanization, should be investigated. Absorption of carbon dioxide from the atmosphere can affect the pH value and conductivity of a sample.

- **Diffusion** – Some fluid samples can have this problem and it is the act of the analyte migrating into and eventually through the container material. It is most noticeable with low molecular weight gases, e.g., hydrogen and helium, with high molecular diffusivities. Liquids also exhibit diffusion, although to a lesser extent. To reduce diffusion, a material should be used to contain the sample that is cost effective, practical, and reduces or does not allow diffusion to take place. Also the sample should be assayed as soon as possible to avoid such losses with storage.

- **Chemical reaction due to chemical instability** – Molecules with labile bonds can decompose under

the storage conditions employed. This can be at ambient, subambient, or frozen temperatures. Reducing the temperature may sometimes stop the decomposition or it may only slow the rate of reaction. Specific tests must be carried out to determine the effects of the storage conditions and the effect on the analyte.

- **Analyte Precipitation** – Certain substances such as colloids that precipitate from solution affect the nature of the sample. Similarly, if the concentration of a compound is near the saturation point, it can precipitate if the storage conditions differ greatly from those at sampling. In some environmental samples, elements may precipitate due to changes in their oxidation state or sulfide formation that may lead to the scavenging or coprecipitating of other elements in a sample.

- **Polymerization and depolymerization** – Polymers can undergo depolymerization after sampling due to chemical and biological causes; conversely small molecules can polymerize. Storage and preservation methods should avoid this happening.

- **Apparent analyte gain** – In biological matrices this can occur when compounds are metabolized *in vivo* to either glucuronide conjugates or N-oxide derivatives. Some of these metabolites may be labile and can revert back to the parent molecule, thus increasing the concentration of the parent over time. This conversion will be seen with a pro rata fall in the metabolite concentration if there is a method available to measure it.

It follows from the areas outlined above that an analyst must be vigilant with respect to the problems that can occur with samples during collection and storage. As stated earlier, an analyst must know the stability of the compound to be measured under the conditions used in the method and the storage conditions under which the sample will be held pending analysis.

## **Storage Techniques**

A specimen must be kept under conditions that preserve the analyte. Some analytes remain stable for long periods, while others require storage at low temperatures, and some others require the addition of preservatives or stabilizers. In some instances, no practical method of preservation may be found.

The extent of these stability problems is a function of the chemical and nature of the sample matrix, its temperature, its exposure to light, the nature of the sample it is placed in, the time between sampling and analysis, and the conditions to which it has been submitted. It is important to minimize extremes of

these conditions and analyze the sample as quickly as possible. The longer a sample is stored, the greater the likelihood that stability problems will be observed.

The storage techniques that are possible for solid, liquid, and gaseous samples are presented below. Owing to the diverse nature of sample matrices, it is impossible to give specific guidance for all samples; therefore a general approach has been taken here with general advice. The analyst should then tailor this for a specific matrix and analyte combination.

### Storage Techniques for Solid Samples

The main forms of samples are usually powders or solids. The first consideration is settling of powders during transportation from the sampling site to the laboratory. The motion of transport should not have the effect of altering the composition of the sample; such an effect may be found with dietary mixtures of feed with a medicated product. The differences in particle size may cause zoning of the medicament. If zoning is suspected, this can be examined experimentally. Transport of solid material may cause breakage by the sample striking the side of the container. Again sample containers should be suitable for the sample to be collected and stored.

Solid samples may have problems with oxidation and, therefore, it may be necessary to remove air by flushing or purging with nitrogen or another inert gas such as argon. An alternative is to fill the container and exclude air, thus avoiding the problem.

Soil samples should be placed into a glass wide-mouthed bottle with a polytetrafluoroethene (PTFE) lined cap. The bottle should be half filled so that the sample can be homogenized before analysis. The samples should be stored in the dark to retard changes due to biological activity. Similarly, the sample containers should be darkened to minimize the effect of light during transport and storage.

Adsorption of the analyte onto the surface of the container is possible, more especially from powdered, than solid, samples. This effect should be examined by stability studies over time and at different concentrations.

### Storage Techniques for Liquid Samples

**Biological samples** The dangers of oxidation, hydrolysis, enzymatic or bacterial transformation, and photodecomposition are usually greater with organic analytes than inorganic ones. The effects are usually concentration dependent that can add to the difficulties of the analysis. With analytes in biological samples they are usually stored at low temperatures to slow down the kinetics of the alteration processes.

This is the most common way of preserving a biological sample. The temperatures used for storage can be subambient (4°C) or deep-frozen (−20°C, −40°C, −80°C, or even under liquid nitrogen). Usually, if a sample is deep-frozen, the temperature chosen will be the most convenient one available, usually −20°C. However, this is no guarantee of stability. Indeed, urine, depending on the amount of salts in a sample, is not completely frozen until −30°C and there are small cells of liquid at −15 to −20°C that may allow some decomposition processes to occur. A storage temperature of −40°C may be appropriate for some analytes in urine.

Often chemicals are added to biological samples to preserve and stabilize some analytes and enhance storage life. These preservatives can act as antioxidants, enzyme inhibitors, or inhibitors of microbial growth. A preservative can have a general action, e.g., ascorbic acid is a general antioxidant and is added in relatively high concentrations in a small volume to plasma to prevent the oxidation of catecholamines such as adrenaline and noradrenaline. At the sample time, a specific preservative, ethylenediaminetetraacetic acid, is added to the same sample to chelate the metal ions used as enzyme cofactors in the metabolism of catecholamines (catechol-O-methyl transferase; COMT). This deprives COMT of the cofactor necessary to function and stabilizes the catecholamines in the samples from *in vitro* degradation by this metabolic pathway. Thus catecholamines in plasma or serum provide an interesting example in the use of specific and general preservatives.

To inhibit microbial growth in blood samples taken for the determination of ethanol, sodium fluoride is added. As a volatile organic analyte is measured, the sample containers should prevent evaporation. Clinical chemistry samples have a variety of preservatives depending on the specific analysis, e.g., heparin or citrate to prevent clotting of a whole blood sample. In this instance the tube already has the preservative in place before the sample is added; all that is required is that the container is gently mixed to disperse the preservative throughout the sample.

Lyophilization (freeze drying) can be used to preserve nonvolatile analytes in liquid samples. The homogenized sample is frozen and the water content is removed over 12–24 h. This is very good for stabilizing some analytes that would be susceptible to enzymic degradation in biological samples and the specimen can then be stored at room temperature without the need for expensive freezer facilities. Analytes that are heat labile can be freeze-dried and then stored as a powder in a freezer. Lyophilization is

useful as the bulk of a sample can be reduced drastically but the process can be time consuming and labor-intensive.

**Water samples** Water can be analyzed for a number of analytes, therefore, the storage conditions and preservatives required can vary. As some changes in samples can occur, certain physical and chemical measurements (temperature, pH value, alkalinity, conductivity, dissolved gases, etc.) are best carried out at the site of sampling to ensure accurate values.

Water samples are usually refrigerated at 4°C for transport to the laboratory and in storage pending analysis. In addition, the sample preservation required depends on the stability of individual analytes. When sample preservation is required there are a number of possible approaches. The pH value of the nonchlorinated water samples can be adjusted by acidification to prevent bacterial growth, biological degradation, or retard acid or base catalyzed decomposition.

Some preservatives, however, present problems in their use. Mercury(II) chloride is used to inhibit bacterial growth. It is effective but has several disadvantages; it is toxic, environmentally unfriendly, and it can interfere with some assays involving activated charcoal where it lowers the recovery of some analytes.

To prevent oxidation, either ascorbic acid or sodium thiosulfate is often added to samples to remove free chlorine that could otherwise form trichloromethane. Polyaromatic hydrocarbons (PAHs), in particular benzo[*a*]-pyrene, are unstable in chlorinated water and sodium thiosulfate is added to preserve the analytes from degradation by chlorine. To ensure stability of the PAH analytes, the water sample is also acidified, again showing that often a single preservative is not always effective for some analytes.

### **Storage Techniques for Gaseous Samples**

The assumption made in this section is that a compound or substance is considered to be a gas if it normally exists in this state at normal pressure and temperature. Excluded from this section are substances that normally exist as a solid or liquid and have sublimed or volatilized due to their vapor pressure.

The most common use for gaseous samples is for environmental monitoring; monitoring the workplace for noxious substances, monitoring a location after a chemical accident, or assessing the level of air pollutants over time. Owing to the physical

nature of gases, there are special sampling procedures used that are related to the technique used for analysis.

There are three main approaches to sampling gaseous samples:

- Direct measurements on site using a portable instrument or a chemical reaction. As this method of monitoring analytes in gaseous samples does not involve sample storage, it will not be considered further here.
- Whole air sample, where a sample is taken and returned unchanged to the laboratory for analysis. This approach is very useful for maintaining sample integrity and where the analyte concentration is sufficiently high to avoid a sample preparation stage before analysis.
- Concentration of the analytes from the air by absorption, adsorption, condensation, or chemical reaction at the site of sampling after which they are returned to the laboratory.

**Whole air samples** Sampling can use glass, metal, or rigid PTFE containers with the neck sealed by a wax-filled cap or a stopcock. Alternatively, plastic bags, made of a variety of inert materials, have also been used. Many parameters can affect the storage of samples. Therefore, the analyst should investigate the storage characteristics of the sampling bags for the analytes being collected. This is achieved by filling the bags with air and injecting known amounts of the analyte. The bag can be sampled over time and the analyte determined to see if there is any adsorption to the bag or diffusion occurs. The results should show no significant drop in analyte over time. If sample bags are reused, they should be checked to see if there are any memory effects from the previous sample. This can be done by flushing the bag with clean air, filling with air, and analyzing after time in storage.

**Concentration sampling** Samples that are concentration sampled have a known volume of gas drawn through or left for a known time for passive diffusion to occur as described in the preceding article. The precautions needed to preserve the sample before storage depend upon the method of sampling. Concentration sampling methods should avoid high temperatures and extremes of relative humidity that may affect the adsorption equilibrium and may promote hydrolysis of some analytes. Where the collection medium is close to saturation, breakthrough of the analyte may occur. In these instances an analyst should know under what conditions this occurs and avoid these extremes; this should be an experiment undertaken during validation of the method.

Where more than one compound is to be collected, there may be the phenomenon of displacement of one analyte by the other. This can be a problem for silica gel as water vapor will displace nonpolar compounds and cause early breakthrough.

**Solid sorbent with thermal desorption** Each cartridge should be thoroughly conditioned by heating and purging with nitrogen for up to 24 h. Most sorbents used are gas chromatography packings, such as Tenax and Porapak, and are stable at the temperatures used for desorption. The thermal stability of the sorbent is very important as decomposition and oxidation of it after repeated reuse and conditioning may cause interference with the analysis. To reduce the background, pretreatment of the sorbent by Soxhlet extraction before packing into the sampling tube can be undertaken. Samples should be analyzed as soon as possible after collection. Storage for up to several weeks may be possible but only after determining the effect of such storage for each analyte.

## Evaluation of Contamination and Analyte Loss

Contamination of the sample must be prevented and degradation of the analytes must be minimized. Even if analyte stability has been fully evaluated and is known, the work of the analyst can be annulled if contamination of the sample is allowed to happen. Again it is the analyst's responsibility to ensure that the samples are taken and stored to minimize any extraneous artifact production or contamination.

### Evaluation of Stability

The stability of the analyte should be known for the normal conditions under which it could be exposed; this should include potential problems that could occur. The analyst should be proactive in this work rather than reactive. The following stability experiments can be undertaken, depending on the nature of the analysis, the analytical method, the matrix, and the analyte.

- The stability of the analyte from the time the sample is taken to receipt in the laboratory must be examined. Two experimental designs can be used, either a sample with a known amount or concentration is prepared or an actual sample with an unknown concentration. In either case, aliquots are taken for analysis at various times after sampling; a plot of the results should show a level display if the analyte is stable or a decreasing concentration if the analyte is unstable. This should identify whether there are any problems with analyte stability; if this

is so, work can begin on conditions that must be used to stabilize the analyte and develop an efficient sampling and preservation protocol.

- Stability during transportation must be tested. Here there are number of factors such as zoning of powders, thawing of frozen samples, which are dependent on the matrix. Investigations into the effect of these factors on analyte stability should be undertaken before large-scale work starts to prevent the wrong conclusions being drawn from incorrect data.
- The problems of long-term storage must be examined. Regardless of the analyte, the length of time that the analyte can be stored without degradation must be known. Long-term storage is a relative term: it can be hours for some analytes or months for others. A long-term stability test should be established under the storage conditions for the samples. If a range of concentrations are measured normally, then two concentrations at the top and bottom should be included. Enough samples should be prepared for a number of replicate (ideally six at each concentration) determinations at intervals over the anticipated storage time. Some additional samples should be prepared in case of a series being lost due to analytical problems or more intervals need to be included after the experiment has started. Again the results should indicate how long the samples could be stored until unacceptable degradation has occurred (say, >10–15%). This time should be the maximum time that the samples could be stored.

### Evaluation of Contamination

Evaluation of contamination is usually through the use of blank samples, i.e., samples that do not contain any analyte. As analytical techniques become more sensitive, and lower and lower concentrations are measured, blank samples are very important. The blank samples aid an interpretation of the result and add confidence. This is important where comparative methods of analysis are used such as chromatography or ultraviolet spectrophotometry. In these instances, the absence of an analyte signal in the blank sample allows an analyst to infer that the signal in the samples and standards is, in fact, due to the analyte.

Blank samples consist of two main types:

- Reagent blanks: these are made up of the reagents used in the assay. The sample matrix is water instead of, e.g., urine and is taken through the method as a sample. The purpose of this type of blank is to identify any contamination that may be due to the reagents used in the analysis.
- Matrix blanks: blank samples should be generated at the same time as the samples themselves, stored

under the same conditions, and taken through the analytical method as if they were samples.

Ideally, reagent and matrix blanks should be included every time a method is used. If this is not feasible then they should be included in a run every time reagents are made up or new batches of chemicals are used, although this does not inform the analyst about the day-to-day operation of the method.

In addition to the blank samples (negative control samples), positive control samples should be considered. These are samples containing a known amount of analyte in the sample matrix. They are included when a batch of samples is taken and stored with them until analysis. In this way there is a marker with every batch of samples to monitor storage conditions and analyte loss.

### Sources of Contamination

There are a number of sources of contamination that an analyst should be aware of, such as the environment, solvent impurities, microbes, and reagents.

**Environment** The environment of the laboratory can introduce contamination in the form of air particles, which may be very important in the case of environmental analysis. The environment of the sample, the sample container, is also a source of contamination. As the container can have an effect on the amount of analyte, it can also introduce contamination into a sample. Typical examples can be plasticizers from plastic containers, including phthalates from stoppers, etc.

**Sample containers and glassware** As discussed earlier, when cleaning sample containers for reuse, much care should be taken. The procedure should not be likely to introduce either contamination or the analyte into the analysis. Therefore when cleaning containers for analysis of volatile organic compound, for example, it would be foolish to use organic solvents as this could introduce the same compound that the method would be measuring.

Contamination can arise from sample containers and apparatus that have been cleaned. The detergents and cleaning agents can introduce contamination that can interfere with an analysis. Cleaning agents that have been tested by examining blanks in the analytical methods can be used routinely. New containers that will be recycled many times should be cleaned thoroughly before use the first time, as there may be dirt and interfering compounds from the manufacturing process or picked up during storage or transport.

**Reagents** Reagents are a source of potential contamination. The use of analytical grade reagents and chemicals is no guarantee of avoiding contamination. Examples of problems with liquid–liquid extraction are typical of the problems facing analytical chemists measuring compounds at the limits of sensitivity. A typical problem can be seen with the stabilizing agents and additives used for solvents.

A problem with liquid–liquid extraction that is often overlooked is the addition of compounds by manufacturers to prevent oxidation or decomposition of their product. For example, to prevent phosgene formation in chloroform, the solvent is often stabilized with 2% ethanol. In itself, this is no problem but when a method is to be established from the literature it may not be immediately obvious to the reader if the solvent contains ethanol (this assumes that the originating author knew the composition of the extracting solvent). The presence of ethanol can change the polarity of the solvent and affect the specificity and recovery of a method.

Diethyl ether can have any one of several chemicals added to it to prevent peroxide formation. These include 2% ethanol,  $2\text{--}3\ \mu\text{g m}^{-1}$  pyrogallol and  $<0.1\ \mu\text{g m}^{-1}$  butylated hydroxytoluene (BHT). Often the addition of a compound is not mentioned in the specification of the solvent. These additive compounds can affect the outcome of an assay. Ethanol, as mentioned above, can affect the polarity of the solvent and hence its selectivity. BHT could be concentrated upon evaporation and form a discrete liquid chromatographic peak, while pyrogallol is electrochemically active and can interfere with a liquid chromatographic analysis when using an electrochemical detector.

**Solvent impurities** The extracting solvent may introduce impurities into an analysis. The term ‘impurity’ is a function of the detection system used in the analytical scheme and the limits of detection required. It may be necessary to redistill or purify the solvent prior to use, e.g., ethyl acetate. Each reagent needs to be assessed for its purity. Moreover, when changing batches, a purity reassessment should be made as it is better to be safe than sorry.

**Microbial contamination** The impact that microbial contamination makes can depend on the nature of the sample and the analysis. Biological samples can be affected profoundly by microbial contamination: ethanol analysis in urine can be affected by elevated levels by microbial contamination. Fluoride is used to inhibit growth and alcohol production. Water samples are similarly affected by the growth of microorganisms for various analytes.

### Automated Sample Preparation

Automated sample preparation can offer a means of improving efficiency and throughput within a laboratory. However, before deciding to implement an automated system, each method to be automated should be evaluated against its objectives, sample numbers, resources, and the amount of time available. Consideration of the physicochemical properties of the analyte, the sample matrix, and the proposed sample preparation technique for isolation will aid the efficient development of robust methods. It is important that the method strategy is thought out and that sufficient time is allowed to think it through. In general, the method used should be the simplest one available that is consistent with the objectives of the assay; it may not involve automated sample preparation.

If automation is viable, the type of automation chosen (e.g., robot, sample processor, or autosampler) will depend upon the expertise and availability within a given laboratory as well as consideration of the items above.

### The Role of Automation in Sample Preparation

Many laboratories ignore a major part of the analytical process that can be rate limiting for many methods and is responsible for a large proportion of

the variation of a method, namely sample preparation. If productivity increases are sought within a laboratory, then there are two possible approaches. The first approach is to change procedures so that tasks are simplified or even eliminated – as such this may not involve the use of automation. However, the viability of this approach can be subject to question unless labor costs are reduced dramatically. The second approach is to use laboratory automation. At the laboratory level, the automation of a task should produce one or more of the following advantages:

- Greater increases in productivity (either in numbers of samples assayed per unit time or speedier turn around time) resulting in overall cost reduction and increased productivity.
- Systems are capable of the same or better precision and accuracy as existing manual methods.
- Trained laboratory staff are free to do more creative or productive work thus improving morale.
- Human contact with biological or chemical hazards is reduced.
- Lower consumption of sample may be possible.
- Lower consumption of reagents used in an automated analysis, resulting in cost reduction and/or reduction of environmental hazard from their disposal.
- Miniaturization of automated sample preparation using microtiter plates containing 96, 384, or higher well capacities.

Instrument automation has been available in various forms for many years. However, the main emphasis of this area of automation used to be toward

### Automated Sample Preparation

Automated sample preparation can offer a means of improving efficiency and throughput within a laboratory. However, before deciding to implement an automated system, each method to be automated should be evaluated against its objectives, sample numbers, resources, and the amount of time available. Consideration of the physicochemical properties of the analyte, the sample matrix, and the proposed sample preparation technique for isolation will aid the efficient development of robust methods. It is important that the method strategy is thought out and that sufficient time is allowed to think it through. In general, the method used should be the simplest one available that is consistent with the objectives of the assay; it may not involve automated sample preparation.

If automation is viable, the type of automation chosen (e.g., robot, sample processor, or autosampler) will depend upon the expertise and availability within a given laboratory as well as consideration of the items above.

### The Role of Automation in Sample Preparation

Many laboratories ignore a major part of the analytical process that can be rate limiting for many methods and is responsible for a large proportion of

the variation of a method, namely sample preparation. If productivity increases are sought within a laboratory, then there are two possible approaches. The first approach is to change procedures so that tasks are simplified or even eliminated – as such this may not involve the use of automation. However, the viability of this approach can be subject to question unless labor costs are reduced dramatically. The second approach is to use laboratory automation. At the laboratory level, the automation of a task should produce one or more of the following advantages:

- Greater increases in productivity (either in numbers of samples assayed per unit time or speedier turn around time) resulting in overall cost reduction and increased productivity.
- Systems are capable of the same or better precision and accuracy as existing manual methods.
- Trained laboratory staff are free to do more creative or productive work thus improving morale.
- Human contact with biological or chemical hazards is reduced.
- Lower consumption of sample may be possible.
- Lower consumption of reagents used in an automated analysis, resulting in cost reduction and/or reduction of environmental hazard from their disposal.
- Miniaturization of automated sample preparation using microtiter plates containing 96, 384, or higher well capacities.

Instrument automation has been available in various forms for many years. However, the main emphasis of this area of automation used to be toward

instrumental analysis and data acquisition and not toward sample preparation. In fact, sample preparation can now be regarded as the weak element in automated analysis for the following reasons:

- Sample preparation was seen to be highly application specific: applicable to one method but not another.
- Variation in the viscosity of some liquid and semi-liquid matrices can lead to variable results, especially when low-pressure pumping systems are used for sample transfer.
- Dilution or concentration steps may be required for some but not all samples.
- The particulate or semisolid nature of some matrices may adversely affect an automated analysis.

However, it has now been realized that some of these points are not major obstructions to automating sample preparation. They have been overcome, and increasing emphasis from users and instrument companies has made automated sample preparation a reality and *de facto* standard in many areas from DNA sequencing to combinatorial chemistry, often combined with the instrumental analysis technique.

Sample preparation is often one of the rate-limiting factors of sample throughput for many methods. Furthermore, it is a critical factor for determining the accuracy and precision of analytical results. The final aim of any sample preparation scheme must be to isolate and purify the compound of interest and present it in a form that is compatible with the analytical instrument. The task facing analytical chemists is to select and use the many diverse systems available, such as robots, sample processors, and autosamplers, to achieve that goal in a timely and cost-effective manner.

### **Islands of Automation**

It is important that a laboratory does not concentrate on simple task automation, such as sample preparation, but develops an overall strategic plan for automating the whole laboratory environment. The reason for this is that analysis is not performed for its own sake, except for educational purposes, but to provide information upon which decisions are made. The purpose of an analytical laboratory is to provide reliable information in a cost-effective and timely manner. To concentrate solely on automating bench-level tasks is inappropriate. The data generated by automated systems have to be interpreted and the resultant information distributed to the organization where decisions will be made.

### **Method Development: When to Automate?**

When developing a method: should an assay be automated immediately or be developed manually first and automated later? While no definite rules can be stated, it may well be easier for methods to be developed manually, first and then automated later. The main exceptions to this statement are column-switching in liquid chromatography (LC) and online dialysis, which can only be developed as automated methods. Another exception is when an existing automated method can be modified easily for use with new analytes, typically those that are structurally similar.

Within an industrial context, time constraints are the main reason for this approach; an assay may be required quickly and a manual method is usually quicker to develop than an automated one. An assay developed first manually allows control to be exercised over the method, its analytical principles and operation can be understood, and trouble shooting problems become easier without the added complication of automated equipment. This approach has the added benefit that results can be generated more rapidly, allowing work to proceed while a procedure is refined and automated.

Attempts to develop automated methods from first principles require that sufficient time, human skills, and resource are available and that these are not critical elements in the method development equation. Therefore, before beginning any work, it is important that sufficient information be assembled to enable a risk and technical feasibility assessment to be carried out on the proposed automated sample preparation method. Thus, it is important that the method selected comprises sample preparation processes that are amenable to automation. The techniques that have the greatest potential for automation are solid-phase extraction and high-performance liquid chromatography. Other sample preparation techniques such as liquid-liquid extraction, protein precipitation, and ultrafiltration are either difficult to automate or may not be cost-efficient to do so compared with alternative approaches.

### **Considerations for Automated Sample Preparation**

To obtain the best from an automated analysis, it is important that only a robust manual method is considered for automation. To use automation effectively, the following factors should be considered before attempting any work on a method.

**Analytical objectives** The following questions should be answered:

- Why is the method being developed or used?
- What questions will be answered by the information generated by the technique?

- How many analytes are to be measured by the procedure now and will this change over time? A method for multiple analytes will involve compromises being made. The number of analytes and their polarity range are factors influencing the choice of both the method of extraction and the whole automated system.
- What is the concentration/amount range over which each analyte is to be measured? If several analytes are to be quantified, each with a different range, this can lead to issues with the design and automation of the sample preparation method.
- For how many different sample matrices will the method be applied and which will need to be validated?

The answers to these questions will give the scope and limitations of the assay procedure. The information provided should enable efficient planning of the approach to take, as modifying a method several times is efficient. This planned approach should also give a better understanding of the total resource required for the work.

**Combine automated sample preparation with analysis** When automating a sample preparation method, strong consideration should be given to combining the automated sample preparation with the subsequent analytical technique. This will ensure that the greatest benefit will be obtained from the effort input. This is discussed in more detail at the end of this article.

**Total sample numbers** The total number of samples to be analyzed can be defined either per year or over the lifetime of a project. There is little point developing an automated sample preparation method for less than 250–500 samples as manual methods can usually be developed and implemented more rapidly. However, when an already established method is available for a structurally related compound, a slight modification may enable an automated method to be developed and validated in minimal time.

**Rate of sample arrival** How will the samples arrive and what is the turn around time required? While the overall numbers per annum may indicate that automation is required, the actual numbers arriving in the laboratory and the turn around time may dictate otherwise, e.g., in a laboratory dealing with emergency poisoning cases, samples may arrive at a continuous rate of a few samples per day, but a rapid turn around is required. It may then be appropriate

to develop an assay that has a simple manual sample preparation and chromatographic separation appropriate to the objectives of the analysis. Conversely, if samples arrive in larger numbers and turn around time is not as vital; an assay can be set up and run when sufficient samples have accumulated to make an automated analysis cost-effective.

**Limit of quantification (LOQ)** What LOQs are required and from what sample volume? Note that the lower the LOQ required for an analysis, the longer the method usually takes to develop; this is true whether an automated or a manual method is being developed.

**Batch size** The number of samples per batch should be considered in relation to the analytical objectives. A large number of batches containing many samples would benefit most from automated sample preparation and analysis as it allows the widest choice for an automated system: robotics, sample processors, or column-switching systems.

**Analyte stability** This factor can have a dramatic effect on the type of automated system used, or in the most extreme example, whether automated analysis can be used at all. Hence, it must be determined early in the method development and validation cycle. If a compound is temperature labile, then the use of cooled sample racks or trays may minimize this effect; if degraded enzymatically an inhibitor may need to be added to prevent breakdown of the analyte pending analysis. Analyte stability can have a profound influence on the number of samples processed per unit time and hence the batch size.

**Matrix composition and effect** Each matrix can have a different chemical composition that can affect the performance of the sample preparation portion in an assay. These must be known and understood for both manual and automated sample preparation methods.

**Matrix consistency** The consistency of a matrix may vary from a liquid to a solid. However, most instrumental techniques require that a sample is liquid for analysis. Therefore, unless the automation includes a liquefaction or homogenization step, most automated systems are usually restricted to liquid samples only. Therefore, some offline manual or online robotic manipulation may be required for some solid matrices.

**Sample preparation technique** The techniques used for preparing the sample for analysis must be

amenable to automation; for example, liquid handling is probably the easiest technique to automate, as there is a wide variety of equipment and approaches possible.

**High-risk samples** All biological samples have the potential to contain infective viruses such as hepatitis or human immunodeficiency virus. Dust and powders can cause serious problems if inhaled. Automation has the advantage that human contact with these types of samples is reduced. However, some automated techniques, e.g., the use of syringes, can generate aerosols containing infectious droplets. Thus, it is important to evaluate the operation of automated systems and house them in appropriate environments.

**Time** The time available can often determine the approaches taken in method development; therefore, it is important to use time effectively and plan the work well. Such constraints may not always be compatible with the development of automated methods. Again this emphasizes the need for a robust manual method to be selected for automation.

**Proposed sample preparation scheme** Knowledge of the physicochemical properties of the analyte can determine many of the techniques that can be used to develop the method, e.g., extraction using functional groups and interactions on the molecule and applicable detection systems. The processes involved in an automated assay should be as simple as possible. Complex automated assays requiring sophisticated online sample preparation and postcolumn reaction detection will take a long time to develop into routine and robust methods.

**Human skills** Never forget the human resource that is available to develop an assay. Do you have the right people to develop the assays you require?

Once these questions have been answered, an analyst is now in a position to make an informed judgment on the probability of success and the risks that are being taken when developing an individual automated sample preparation method. In fact, now the analyst has the information to decide when and why an automated method should be developed and perhaps, more importantly, why not and when not to develop such methods.

## **Factors in Design of a General Automated Sample Preparation System**

After an automated sample preparation method has been justified (by the criteria above), three factors

must be considered in the following order for the design of a suitable automated sample preparation system:

1. the consistency of the sample matrix,
2. easily automated sample preparation techniques, and
3. the appropriate automated instruments or systems.

Again, thought is required to design an automated sample preparation scheme for an individual analysis.

### **Matrix Consistency**

Sample matrices are liquid, semiliquid, or solid. The matrices that are easiest to incorporate in automated sample preparation schemes are liquid or semiliquid ones. As noted earlier, most analytical instruments require a liquid sample. Moving liquids, even relatively large volumes, can be easily accomplished by using syringes, sample loops, and low-pressure pumps. There may be a need to remove particulate matter from a sample prior to cleanup and this may be automated or done offline.

Semiliquid samples, such as plasma, can use to an extent the same techniques as liquid samples. Some samples usually need dilution to ensure that differences in viscosity between samples are minimized. Again, this can be done offline or by the sample processor.

Solid samples, varying from rocks, through tablets to biological tissues, can present a major problem for automation. The physical form of the sample can limit both the technique and the instrument that can be applied. This is an area that needs radical thought to solve the problems posed by the sample. For example, the automated microwave digestion of minerals still requires the crushing of the rock to be a manual offline process. To automate this and eliminate cross-contamination may not be easy or cost-effective.

### **Sample Preparation Techniques Amenable to Automation**

The major sample preparation techniques that are amenable to automation are solid-phase extraction, LC, dialysis, microwave sample preparation, flow injection analysis, and segmented flow analysis. Other sample preparation techniques, such as liquid-liquid extraction or ultrafiltration, may be possible to automate but may not be cost effective. This shortlist of amenable techniques may constrain an analysis, but there is a large body of experience in the literature to help a novice to use these procedures.

## Automated Instruments

Some automatic sample processors are also analytical instruments such as LC, flow injection analyzers, or autoanalyzers. There is a trend, wherever possible, to merge the sample preparation technique with the instrumental analysis. This allows greater efficiency and productivity. In addition, there are robots and sample processors that can be used to automate sample preparation.

Automated instruments can be classified into two main types, flexible and dedicated:

- Flexible automation can be reprogrammed but also reengineered to change the task that can be undertaken by it. This type of automation is typified by robotic arms.
- Dedicated automation is usually limited to a specific task, which may be varied by programming or parameterization of the basic commands of the program controlling the instrument. This can take the form of autosamplers, autoanalyzers, or batch processors, and these can offer a cost-effective means of automating an instrument assay. These autosamplers can automate techniques such as solid-phase extraction or dialysis.

## Classification of Automated Sample Processing

The operations comprising an analytical process have to be performed in the same sequence for each sample and in an identical manner. However, when a number of samples are to be analyzed, they can be either batch or sequentially processed. Refinements of these approaches to give shorter process times are parallel batch and concurrent sequential processing.

### Batch Processing

In batch processing, each single operation in the analytical process is carried out on each sample before the next operation is performed. Most manual techniques employ batch processing, due to the convenience of performing a single operation many times. The total time taken to process a group of samples is equal to the sum of the times for each unit operation in the analysis multiplied by the number of samples in the batch.

There are a number of disadvantages of batch processing. When the time taken to perform each operation are not identical then the time interval between the operations performed on each sample will be different, i.e., each sample does not receive identical treatment with respect to time. When the analytical process fails, all the samples in the batch are

lost. A high-priority sample cannot be analyzed preferentially since all the samples are treated in one batch.

### Sequential Processing

Each sample individually receives treatment from all of the operations before the next sample in the sequence is analyzed. Priority is given to the completion of all operations on a single sample and at any time only one sample is ever present in the analytical process. The total time taken to process a group of samples is equal to the sum of the times for each unit operation in the analysis multiplied by the number of samples in the sequence, i.e., the same as for batch processing. The disadvantage of sequential processing is that the timing of the operations must be very precise to ensure identical treatment of each sample.

### Parallel Batch Processing

When employing batch processing it is usual, in some of the operations, for the batch of samples to be treated in parallel, e.g., centrifugation, incubation with reagents, mixing, or passing liquid through solid-phase extraction columns with the assistance of vacuum or compressed gas. Parallel processing consideration reduces the total process time. The time saving increases with the number of samples in the batch.

Any errors due to variation in the length of treatment are eliminated because by parallel processing all the samples in one batch are treated simultaneously. It is important to ensure that the treatment actually starts at the beginning of the parallel treatment and finishes at the end of it. A further problem with parallel batch processing is monitoring the function of the operation. If an operation fails to function, all the samples are affected.

### Concurrent Sequential Processing

With concurrent sequential processing, as a sample passes along the chain of operations, further samples enter the system so that multiple operations function simultaneously. Once the system is running, the number of samples being treated at any one time is equal to the number of operations running concurrently and it is only these that will be lost in the event of a failure. The reduction in total processing time is proportional to the number of operations running concurrently and is independent of the number of samples being analyzed.

Of the four different types of processing, concurrent sequential processing requires the most complex system controls to coordinate the concurrent operations. Additionally, if the duration of the concurrent

operations is different, then, with respect to time, the first sample receives different treatment than do the subsequent samples. To speed up automated analysis, scheduling algorithms can be used.

## **Applications of Automated Sample Preparation**

Two applications will be described to illustrate automated sample preparation. The first will outline the automation of microwave dissolution of minerals, a solid matrix. The second will describe the use of online LC for the determination of urapadil and its metabolites in human plasma.

### **Robotically Controlled Microwave Dissolution of Minerals**

There are many ore samples that require analysis to guide mining operations and control the metallurgical processes for metal recovery. Despite advances in instrumentation, the sample preparation used is a lengthy manual acid digestion with nitric and sulfuric acids. Labrecque described a technique in 1988 for using a microwave oven to speed up the acid digestion of minerals. Showing the principles above, a manual microwave method was developed and automated using a commercially available robot arm. The robotic system took previously crushed and powdered ore samples and weighed an aliquot, added the appropriate acid reagents, capped the digestion vial, and then put the vial into a microwave oven. When the digestion was completed, the robot took the vial from the oven and placed it in a rack to cool.

This method illustrates a number of points on automated sample preparation. First, a new technique was needed to automate the preparation of a solid matrix. Second, not all of the methods could be automated in a cost-effective manner as the samples were powdered under human control. Finally, the sample preparation was standalone: the extracts were manually transferred to the analytical instruments.

### **Analysis of Urapadil in Plasma by Online LC**

This automated method involves the direct injection of a measured aliquot of plasma by an autosampler into a liquid chromatograph. A precolumn is used to trap the urapadil and its metabolites and wash the majority of the interfering plasma components to waste. A valve then switches the precolumn inline with the analytical column and the analytes are washed off the precolumn and separated by the analytical column. During the analysis, the precolumn is reconditioned to accept the next sample.

The sample in this method is a semiliquid and therefore it is easier to automate and to combine both the sample preparation and analysis into one operation. Furthermore, the cost of this system is little more than the additional switching valves over the chromatograph needed for a manual method. If the data system is combined with a laboratory information managing system (LIMS) virtually the whole of the analytical method can be automated.

## **Integrated Automatic Methods**

The principle that sample preparation should be performed automatically is almost universal and is independent of the instrumental technique. However, most so-called automatic methods are not truly automated – they are just mechanized. Most automated sample preparation systems have three factors missing: integration, equipment control, and communication.

Integration of sample preparation with the rest of the analysis is essential for full productivity gains to be achieved. This is achieved with some automated sample preparation techniques, e.g., LC column-switching illustrated above. The trend in automated sample preparation is clear: the technique will be online and part of the instrumental analysis. To use this approach, the sample must be liquid before the analysis can commence. Therefore, more effort needs to be spent investigating how to automate the sample preparation of solid samples.

The second factor concerns control of automated systems: what happens if there is a malfunction? At present, few automated sample preparation systems offer overall control. The probability, in the event of a malfunction, is that the autosampler will complete its cycle and valuable samples will be lost. Thus, developers must consider feedback control mechanisms that are essential to monitor the operation of a complex instrument that would be sampling, preparing, and analyzing simultaneously. If an error in this operation were detected and if the fault could not be corrected, the unit could be shut down, thus preventing the further loss of any samples. The development of these workstations able to make decisions may involve chemometrics, where there will be feedback between the analytical measurement and the experimental design.

The final factor is communication. Bidirectional communication with an LIMS is essential to produce an integrated sample preparation workstation for the analytical laboratory. Communications must be incorporated so that the workstation should be able to receive instructions such as the method and the

analysis conditions and the sample identities. When achieved, the checking for transcription error and administration for an analysis would be reduced drastically. When the analysis is complete, the LIMS receives a file with the sample ID and the corresponding analysis results for incorporation in the laboratory database. Failure to incorporate these facilities will mean that advances in automated sample preparation will be slow.

## Introduction

Even though pick-and-place robots had been in use for some time previously, commercial laboratory robots were first introduced at the 1982 Pittsburgh Conference by the pioneering firm Zymark Corporation. By 1994, robotics had seemingly reached maturity, so a specific nomenclature for laboratory robotics and automation was issued by the International Union of Pure and Applied Chemistry (IUPAC). Some of IUPAC's recommended terms are general and require the word 'robot' or 'robotics' for specific use (e.g., in 'controlled-path robots', 'corrosion-resistant robots', 'feedback in robotics', 'accuracy in robotics'); others are characteristic of robotic technology (e.g., 'arm', 'articulate structure', 'flexible automation', 'manipulator').

A robot (the name comes from the Czech word 'robota', which means work or servant) can be

defined as 'an automatically controlled, re-programmable, multipurpose, manipulative machine with several degrees of freedom, which may be either fixed in place or mobile for use in automation applications' or, more loosely, as 'a multipurpose machine which, like a human, can perform a variety of different tasks under conditions that may be unknown *a priori*'. The different types of robots currently available can be classified according to physical features such as hardware construction, degrees of freedom, coordinate system, or level of sophistication and technology.

The initially envisaged uses of a robot in the laboratory – which led several renowned manufacturers to fail in the past – have changed with time. At present, robots are devoted to things that users can hardly figure out how to do easily in any other way. These unique needs range from massive robotic systems for handling thousands of samples produced in high-throughput drug discovery and biochemical study programs to standalone devices that drone away at repetitive tasks.

Depending on both the number of tasks to be performed and their complexity, users can currently

analysis conditions and the sample identities. When achieved, the checking for transcription error and administration for an analysis would be reduced drastically. When the analysis is complete, the LIMS receives a file with the sample ID and the corresponding analysis results for incorporation in the laboratory database. Failure to incorporate these facilities will mean that advances in automated sample preparation will be slow.

## Introduction

Even though pick-and-place robots had been in use for some time previously, commercial laboratory robots were first introduced at the 1982 Pittsburgh Conference by the pioneering firm Zymark Corporation. By 1994, robotics had seemingly reached maturity, so a specific nomenclature for laboratory robotics and automation was issued by the International Union of Pure and Applied Chemistry (IUPAC). Some of IUPAC's recommended terms are general and require the word 'robot' or 'robotics' for specific use (e.g., in 'controlled-path robots', 'corrosion-resistant robots', 'feedback in robotics', 'accuracy in robotics'); others are characteristic of robotic technology (e.g., 'arm', 'articulate structure', 'flexible automation', 'manipulator').

A robot (the name comes from the Czech word 'robota', which means work or servant) can be

defined as 'an automatically controlled, re-programmable, multipurpose, manipulative machine with several degrees of freedom, which may be either fixed in place or mobile for use in automation applications' or, more loosely, as 'a multipurpose machine which, like a human, can perform a variety of different tasks under conditions that may be unknown *a priori*'. The different types of robots currently available can be classified according to physical features such as hardware construction, degrees of freedom, coordinate system, or level of sophistication and technology.

The initially envisaged uses of a robot in the laboratory – which led several renowned manufacturers to fail in the past – have changed with time. At present, robots are devoted to things that users can hardly figure out how to do easily in any other way. These unique needs range from massive robotic systems for handling thousands of samples produced in high-throughput drug discovery and biochemical study programs to standalone devices that drone away at repetitive tasks.

Depending on both the number of tasks to be performed and their complexity, users can currently

choose between robotic stations and workstations. The former automate the entire processes; they often include facilities for sample insertion into analytical instruments and use the typical arm and an array of modules and peripherals to make tasks easier for the robot. Today, manufacturers design arms to function as ‘movers of stuff’ and operations such as transferring or filtering solutions are handled in modules around them. Workstations represent a newer vision of robotics. They are custom automation tools that assist workers in performing their job better and more efficiently. These stand-alone automated units are used for specific purposes such as handling liquids or preparing solid samples; they are growing in popularity as they can perform one to three tasks with reduced costs and sophistication. Some workstations can be interconnected or operated with robotic arms, while others use their own, dedicated arms (particularly to handle solid samples). One of the main differences between robotic arm systems and workstations is cost, the workstations being more economical, although this fact depends on its level of sophistication.

Because robotic technology continues to have some magical connotations in relation to laboratory automation, a number of manufacturers and users still use the words ‘robot’ and ‘robotic’ interchangeably to refer to both robotic stations and workstations. In addition, any instance of automation is also indiscriminately associated with robotics by many.

## Workstations, Robots, Modules, and Peripherals

The most salient difference between robotic stations and workstations is that, whereas a workstation can only be used for the tasks (all or some) for which it was constructed, robotic stations can be modified by changing their software, modules, or peripherals as required to undertake one or more specific tasks, or even a whole analytical process. As a result, describing a workstation is as simple as listing its intended functions, whereas characterizing a robotic station includes stating the type of arm it uses and the equipment that helps the arm perform its tasks.

Figure 1 depicts the scope of application of each option in terms of task complexity and throughput.

### Workstations

The most simple and common workstations are those for dilution and/or reagent addition to a number of samples in a simultaneous manner, either to all

**Figure 1** Fields of application of workstations and robotic stations according to task complexity and throughput. (Reproduced with permission of Elsevier Science.)

samples in a rack or to a line with a slide z-axis. Most workstations are designed to operate with liquid samples with specific equipment for liquid handling, solid-phase extraction, and preparation of liquid samples for insertion into chromatographs.

While considering solid samples, one alternative can be the use of workstations for automatic dissolution, which are very common in pharmaceutical dissolution testing. So, they can also be used to weigh and dissolve (or leach) some specific types of solids. However, there are workstations capable of automating solid sample treatments, including options as weighing, mixing, filtration, homogenization, and solid-phase extraction of samples for automatic insertion into chromatographs or transfer to other detection systems.

Figure 2 shows the tablet processing Zymark workstations, which was designed for treating solid samples.

### Robots

A laboratory robot constitutes the most flexible tool for automation as it can reproduce, with minimal adaptation, almost every task performed by an analyst.

A laboratory robot is essentially a machine consisting of various parts, namely:

1. The ‘manipulator’, which is a mechanism for grasping and/or moving objects, usually in several degrees of freedom. The essential parts of the manipulator are the body, the arm and a hand or end-effector.
2. The ‘controller’, an information processing device whose inputs are both desired and measured position, velocity, and other pertinent variables of the process. The robot can be controlled by the user, in a point-to-point manner and by a computer otherwise. The last are more common – ‘power

**Figure 2** Tablet processing II model Zymark workstations for solid sample treatment. (Reproduced with permission of Zymark Corporation.)

and event controller' (PEC) – and benefit from continuous improvement derived from the development of new software programming languages.

3. The 'power supply', which provides the energy – usually electrical or pneumatic energy sources – for locomotion of the different manipulator parts.
4. 'Sensors', which are used to boost performance in intelligent robots. They can be sorted according to type, physical and computational foundation, fixed or mobile and of the contact (force and tactile sensors) or noncontact type (vision, proximity, and range sensors).

One of the most important features of a robot, which determines its work envelope (i.e., the maximum extent and reach of the robot) is its position in the robotic station, which can be fixed or variable. The former is used in circular robotic stations, where the robotic arm is in the center of a circle and the different peripherals are included in a work envelope radius as removable pieces of a pie. An example can be seen in Figure 3.

A mobile arm in a robotic station is supported in a track that allows displacement of the arm in a length that varies, depending on the particular station, from 1 to 2 m. The capacity of the robotic station for locating peripherals in the work envelope of the arm can be expanded by using a more complex arm capable of operating on both sides of the track.

### Modules and Peripherals

The modules of a robotic station are the devices (apparatus, instruments, racks) used by the arm to perform its tasks. In circular configurations, the modules are referred to as 'peripherals'.

**Figure 3** Circular, PyTechnology, robotic station with fixed arm from Zymark. (Reproduced with permission of Zymark Corporation.)

The number of modules present in the work envelope of a robot arm varies with the number of tasks it is to perform in a given process. Some modules can be as complex as self-contained workstations. Although most of the modules required for the different steps of the process can be provided by either the arm's or an alternative manufacturer, some users design and construct their own modules, either because of the high specificity of the task or with a view to reducing costs.

The 'balance' is the most important module of a robotic station in dealing with solid samples. The only way of automating weighing is by using a robot or workstation. The balance must be connected to the PEC and be accessible to the robot arm, which should be furnished with a special end-effector or hand (a gripper hand) and a powder-pouring device (usually vibration based). Weight-based

measurements of liquids are frequently used in robotic stations as they provide more accurate data than do volume measurements. Zymark's new automated filter weighing system is an excellent example of the use of the balance with gaseous environmental samples. It provides automated and exact repetition of the analytical steps for compliance with EPA PM2.5 methods and uses no external air source in order to avoid introducing contaminants; also, filters are located before and after each weighing, and also ion-discharged before weighing.

A 'dissolve and dilute' module is a dual peripheral that includes a vortex mixer to facilitate dissolution and the obtainment of a homogeneous solution, respectively.

A 'master laboratory station' (MLS) is a module consisting of three syringes for dispensing liquids in conjunction with the dissolve and dilute module. However, the MLS can be used for additional purposes such as aspirating the phases involved in a liquid-liquid extraction (using a different syringe for each phase).

A 'centrifuge' is a key module when solid samples are to be leached or a precipitate forms during the process. The use of sensors to ensure correct positioning of the tubes with respect to the robot before and after the centrifugation step is mandatory here. Computer vision and neural networks can be used to detect errors in a robot system performing the automatic loading and unloading of a centrifuge.

'All-purpose hands' and 'syringe hands', available in a variety of designs, are also required elements of a robotic station. Differently sized objects (e.g., sample flasks, test tubes, probes, hold and press push-buttons) call for also different types of hand. A syringe hand facilitates the withdrawal of liquids from vessels.

'Liquid-liquid', 'solid-liquid', and 'liquid-solid' extraction modules are also devices required for implementation of a number of methods.

'Racks' can hold a variable number of test tubes, the positions of which are numbered so that the robot can distinguish them. In addition to holding the tubes, racks can accommodate devices such as the aspirator assay probe or even the sample probe if one is used.

Additional modules not always required in a robotic station include a 'capping-uncapping' module, used to remove and replace screw caps; a 'barcode reader', which is usually a laser barcode scanner combined with a turntable assembly capable of reading a label positioned anywhere around the circumference of a vial; and an 'ultrasonic bath', which is required not only for sonic mixing or cleaning,

but also, occasionally, to facilitate dissolution or leaching.

The performance of robots in some processes can be improved by using various approaches to expedite one or more steps thereof. One such approach involves adapting nonautomated devices for automated use in a robotic station; for example, the use of microwave digesters, which substantially accelerate solid sample pretreatment.

Robot control is a current research topic, which encompasses new hardware concepts for robot control, software environments for optimizing the productivity of robotic laboratories, and dedicated software for use in environmental laboratories. Finally, simulation and graphical animation of robots is highly useful with a view to both optimizing robot work and avoiding catastrophes on the workbench. Incorporating robotic stations into large-scale laboratories entails establishing appropriate links with a laboratory information management system (LIMS) to ensure precise control of the laboratory as a whole.

## **Detectors**

One of the essential units for completion of the overall analytical process by an automated system is the detector, which cannot be considered a module or peripheral as it preserves its identity as such and is only connected to the PEC for switching on, instrumental variable programming, and data collection. The robotic arm acts as a bridge between the other steps of the analytical process and detection, either by inserting the treated sample into the detector or by connecting the treated sample with the detector via fiber optics (occasionally furnished with a sensor) or electrical wire.

Photometric detectors are the most common choice for monitoring the end product of a robotic station. The easiest way to detect products here is by using an optical fiber to drive the beam from the light source to the solution under study, with passage through it and then back to the detector.

Luminescence molecular detectors have also been used for online monitoring of dissolution tests and the characterization of toxic residues using bioluminescence assays. Atomic (atomic absorption spectroscopy, inductively coupled plasma-atomic emission spectroscopy (ICP-AES)) detectors have been coupled to robotic stations either through a continuous system acting as interface or by direct aspiration into an instrument from a sample vial following treatment by the robot. Mass spectrometric and nuclear magnetic resonance (NMR) detectors

used in this context are also based on direct aspiration.

Electrochemical detectors (particularly probe sensors) are also widely used in robotic stations; for instance, the determination of soil pH by inserting a glass electrode into a test tube containing the soil leachate. A straightforward washing-rinsing station allows cleaning of the electrode, which is fouled in the measuring operation. A conductivity detector can also be used to determine soil salinity.

Finally, a balance can be used to develop a gravimetric method, for example, the determination of the oxidative stability of olive oil.

### Miscellaneous Considerations on Workstations and Robotic Stations

Two essential facts to be considered in purchasing a robotic station are that no single firm builds everything; there is a need to construct a robotic system tailored to one's needs, and compatibility between modules from different sources should thus be carefully checked prior to purchasing.

Procurement of supplies (pipette tips, autosampler vials, filters, etc.) and waste disposal are also two important issues in setting up and maintaining a robotic laboratory.

Because workstations can be designed and dedicated to a single, specific task, they are normally simpler mechanically and usually more reliable than are robotic stations. In addition, they can provide a data trail for regulatory compliance and are typically designed to be operated by non-experts. Commercial workstations vary in their level of sophistication, which allows the automation of even the simplest procedures.

Workstations operate best when there are one to three functions being automated; more operations or less defined analytical steps require the sophistication of robotic arm systems, which are more flexible and work best early on in research, when the methodology is not well defined.

Choosing between a robot plus peripherals and a workstation is a difficult task. From the beginning, automation held the promise of freeing analysts from cumbersome, time-consuming, repetitive tasks. In a quality control (QC) laboratory, workstations are typically the best solution as they are often more 'hardwired' and are better in QC laboratories, where the analytical steps are well understood and this equipment does save the laboratory's time and money. The best solution for implementing the complex treatments required by some solid samples is the sequential use of two workstations; when this is

impossible, a robotic station is the next-best choice in most instances.

## The Role of Robots in the Analytical Process

Automation of the analytical process by use of robotic equipment can extend from a single step to the whole analytical sequence. The number of steps that are robotized should be dictated by the user's experience and judgment, always as a function of the target process, costs, number of samples to be processed, etc. Straightforward single-task uses of robots, robotic sample preparation procedures, and fully robotized methods are discussed below, as are more rational uses in combination with other techniques intended to ensure optimum development of each step of the analytical process.

### Single-task Robots and Simple Uses of Robotics

One of the most important reasons of failure at the beginning of the laboratory robotics era, when no workstations were available, was the use of large robots to perform a single, repetitive task such as weighing, diluting or solid-phase extraction. One of the most common single tasks assigned to robots is weighing – the analytical step most difficult to implement using alternative automated approaches. Automating laboratory weighing may not increase the speed of weighing, but can free the valuable time of scientists and technicians.

Zymark has proposed simple and inexpensive workstations designed for specific tasks. Furthermore, some noncommercial systems for single tasks include a microwave digestion system for dissolution of Ti(IV) oxide and adaptations of workstations for special tasks such as the robotic–chromatographic method for the determination of glycosylated haemoglobin.

### Sample Preparation

Sample preparation is the most general application of both workstations and robotic stations as the tasks involved in this step of the analytical process are the most time-consuming, error prone, and difficult to develop by unskilled operators; in addition, safety restrictions apply when toxic materials are to be handled. The use of a specific approach depends on the number of steps involved and their complexity. **Table 1** summarizes the features of selected general and specific sample pretreatment procedures used in the environmental and clinical fields. Whereas most environmental samples subjected to a robotic treatment are solid, those dealt with by clinical

laboratories are typically liquid and highly complex in nature, as can be seen. The type of analyte to be isolated from a given sample and the main operations to be performed by either the workstation or the robot to prepare the sample for subsequent steps, as well as the main steps following the treatment, are also listed in **Table 1**. When the step following treatment of the sample is insertion into a highly discriminating instrument such as an NMR or MS/MS instrument, the robotic station is aimed at a 24-h working day of the high-price instrument in an

unattended manner, thus avoiding either the high maintenance personnel costs of continuous work or the purchase of another instrument. This task even justifies the use of a simple robotic station to insert samples with noncomplex matrices into the instrument.

Although workstations and even robotic stations commonly perform liquid–liquid and liquid–solid separations, these steps can be implemented in a continuous manner by using a more inexpensive setup and with shorter development times when the number of samples is not very high and the results

must be available within a short time. The unit operations that can be performed failure free by a robot include weighing, centrifugation, filtration, and special instances of solid and liquid transfer. On the other hand, reagent addition, dilution, heating, homogenization, derivatization, and insertion into a measuring instrument are generally more rapidly, economically, and efficiently performed by other automated alternatives, whether continuous or discrete.

### **Robotic Development of the Whole Analytical Process**

Most frequently, using a robotic station to develop an entire analytical process is unwarranted. However, well-established criteria exist to ensure correct use of the potential of robotic technology.

One well-justified use of a robotic station is in the gravimetric method for the determination of the oxidative stability of olive oil, where the station monitors the amount of oxygen absorbed by a sample heated under controlled conditions. The method was intended to relieve the typically heavy workload of olive oil analysis laboratories in winter and involves weighing the samples in test tubes that are heated for a few hours, allowed to cool and then weighed, the cycle being repeated as many times as required, depending on the stability of the oil, until the weight gain of all samples reaches a preset value.

Other example is the determination of fuel parameters including the diene value and mercaptan sulfur. First, the robot weighs the sample, refluxes it in the presence of maleic anhydride, and extracts the analytes into an aqueous phase, which is poured into the titration vessel, where the robot inserts the photometric or potentiometric probe. For the determination of mercaptan sulfur, the robot also weighs the sample and removes sulfide by precipitation with a  $\text{CdSO}_4$  solution and liquid-liquid extraction. Once the fuel is sulfide free, which is checked by using a photometric probe, it is poured into the titration vessel by the robot arm, which also plunges an Ag electrode prior to addition of the titrant (an  $\text{AgNO}_3$  solution). In both cases, the automated titrator acts as a module of the robotic station and is operated by the robotic arm.

### **Combining Robotic and Continuous Systems for More Reliable Development of the Whole Analytical Process**

The 'bridge' spanning the raw sample and reading of the analytical signal, which is a function of the analyte concentration, has traditionally been built around single batch, continuous, or robotic methodologies for driving the sample to the detector. Each

approach has its own advantages and disadvantages, and no single currently available choice for automation is the panacea. Combinations of a robotic station or a workstation with a liquid or gas chromatograph, or a capillary electrophoresis instrument, have been reported in which an autosampler was used as an interface, the robot arm either placing the vials in it or loading them (following positioning on the autosampler) with the treated samples.

Users experienced in flow injection (FI) methodology have proposed this continuous approach as the most easygoing friend of robotics in order to take advantage of both. Thus, the expeditiousness and simplicity of FI systems are offset by their inability to automate certain operations (some so essential as weighing); on the other hand, robots, which are the most powerful systems as regards the variety of processes they can develop, have an inherent relative slowness compared to FI systems in addition to a high purchase cost. However, the complementary features of the FI technique and robotics warrant their joint use with a view to exploiting their respective advantages while avoiding their shortcomings in isolation.

Combined FI-robotic systems can in principle be used in two ways, namely: (1) by having the two individual systems operate independently of each other, the user acting as an active interface between both, and (2) by setting up an integrated system where the two subsystems will interrelate to eliminate the need for human intervention. In the former approach, the robot is devoted to automating the complex preliminary operations the FI system cannot handle (e.g., placing partially treated samples in a rack for subsequent transfer to the FI system by the user); the FI system acts as an automated device for inserting samples into the instrument, with or without a prior separation and/or derivatization step. There are few reported instances of the combined use of an FI manifold and a robotic station operating independently. One application is the automation of a method for the determination of total vitamin C in foods. Here, the robotic station is used for homogenization of the sample, weighing, addition of an extractant, centrifugation, filtration, and cleanup through a  $\text{C}_{18}$  column. After this treatment, the sample is manually transferred to the FI autosampler. A derivatizing reaction is implemented along the FI manifold to obtain a fluorescent product prior to insertion into the spectrofluorimeter. Although not specifically stated, the information produced is also transferred manually between both systems. The previous example illustrates a way of transmitting information in offline coupled FI-robot systems,

namely: automatic processing by means of an online microcomputer or manual acquisition and treatment.

In the integrated approach, the FI manifold is a module of the robotic station that is used to insert the sample into the detector (also with or without a prior separation and/or reaction). This latter approach involves no human intervention, which is an obvious advantage with respect to the former.

Even when the tasks to be conducted in the FI manifold are simple, coupling it to a robot provides some advantages. One example is the fully automated method for the determination of metals in soil. The use of a two-channel FI manifold to introduce robot-treated (weighed, microwave-digested, centrifuged) samples into the measuring instrument (e.g., an atomic absorption spectrophotometer) enables real and pseudodilutions with a dramatically broadened calibration range. In this way, the need for a prior estimation of the analyte concentration is avoided. In addition, such an expensive peripheral as a syringe hand is replaced with an inexpensive manifold, which reduces purchase costs. The overall operational setup for solid sample pretreatment plus determination is shown in Figure 4.

## Analytical Scope of Application of Robotics

Although robots can be used in virtually all analytical areas, its major applications encompass the clinical, pharmaceutical, and biotechnological fields.

The original robot arms gradually have replaced the well-known air-segmented continuous autoanalysers, mainly from Technicon in clinical laboratory and were eventually superseded by workstations for specific tasks such as pipetting, diluting, reagent addition (i.e., sample-handling tasks). Dedicated clinical laboratory workstations are used to receive samples in capped, barcoded vials in an indexing holding rack that the robot decaps in a decapper and introduces into the analyzer(s) as a function of the specific bar code. The use of robots in the healthcare sector is not limited to the clinical laboratory; in fact, it also encompasses tasks such as the assistance to surgical procedures, the elimination of mundane chores and the reduction of exposure of personnel to communicable diseases.

The pharmaceutical field has exploited robotic stations for the main purposes of dissolution testing and drug design. In fact, most of the procedures described in robotic manuals are concerned with the determination of drugs in pharmaceutical preparations. Robotic stations as such were initially also programmed for such a simple use as dissolution testing. Later, workstations for dissolution testing have flooded the market with specific designs in variable degrees of sophistication (e.g., for continuous monitoring through fiber optics, insertion into a chromatograph). In any case, robotic stations continue to be used to develop innovations in the pharmaceutical field. The impact of robotic high-throughput screening on drug discovery is a consequence of its ability to screen up to 100 000 samples

**Figure 4** Robotic station for fully automated determination of metals in soil. (---) Passive interface. (—) Tubing. Active interfaces of the computer to the robot and its peripherals are not shown. (Reproduced with permission of Elsevier Science.)

per day per instrument; this in turn results from the demand for new compounds, which is being met by combinatorial chemistry the most important pharmaceutical use of robotics at present.

Biotechnology is no doubt the most rapidly expanding field of application of robots. Most robotic biotechnological research work is conducted by workstations. Accelerated recombinant protein purification processes have been developed by using a workstation equipped with a fully integrated sample-holding robot that allows preparative cation-exchange chromatographic runs to be completed and the collected fractions analyzed by high-performance liquid chromatography (HPLC).

Various other fields benefit from the use of robotics. For example, the unstoppable advances in robotic technology have led to the development of a microrobotic arm constructed by using lithographic techniques that can be mobilized in an aqueous environment to pick up, lift, and reposition a 100- $\mu$ m glass bead. Agricultural laboratories are increasingly taking advantage of the use of robotics as seasonal overloads call for a 24-h working day without the involvement of temporary personnel. Thus, tasks such as weighing, leaching, filtering and measurement are frequently performed by robots in the determination of parameters such as pH, organic matter, conductivity, lime and phosphorus in soil, or bitterness in virgin olive oil.

## Present and Future Status of Robotics

Robotics as implemented in workstations and robotic stations has proved to be one of the most accurate and autonomous automated facilities, a fact that directly influences both the productivity and the quality of the analytical results it provides. However, despite the continuous advances, further expansion of robotic technology has been met with several serious hindrances, namely:

1. The scarcity or even lack of standards for checking and/or validating unit operations which led the official endorsement of a robotic method.
2. The high purchase cost of robotic stations, which makes them inaccessible to small laboratories – workstations are usually more affordable.
3. The need of professional assistance both from the manufacturer and dedicated specialists to keep robotic equipment operational.
4. The scarcity of literature on robotics, which is a consequence of the limited use of robotic equipment for research purposes outside companies while the results of private research teams are

rarely published in scientific journals. Moreover, propaganda publications magnifies advantages of robotics and hardly explains the underlying principle or working programs.

Current R&D efforts in robotics are being aimed at overcoming these weaknesses and provide clues for a number of strategies to be adopted in the future, namely:

1. Cooperative alliances between robotics firms and other manufacturing companies.
2. The current drivers for new robotic technology are the high-throughput screening and combinatorial chemistry markets.
3. Experts also expect automation to become more sophisticated through adoption of new technical achievements in both this area and computer science, which are being incorporated day by day to new equipment.
4. The simultaneous treatment of several samples in different analysis steps will be increasingly fostered in the future.
5. Robots will be driven to work in smaller dimensions (e.g., those of a 384-well plate) as they are still too large to deal with the increasingly smaller samples involved in clinical analyses. A saving of reagents will be one immediate result of this trend.
6. Internal and/or external sensors will be mandatory in order to construct robotic stations capable of performing new tasks (e.g., establishing when a solid sample has been completely dissolved, detecting the presence or appearance of a precipitate) and develop mobile robots. These can be either used in isolation or incorporated into robots or robotic stations in order to ensure traceability in the results by use of well-established barcoding systems.
7. The true revolution in analytical robotics will probably come from the development of artificial intelligence. Future robots will be managed by expert systems in such a way that they will be able to find solutions to analytical problems by using both the initial stored information and that obtained from the process it has developed previously. The use of artificial intelligence and neural networks to integrate laboratory automation will be one of the most exciting areas in future robotics research.

In this way, small laboratories will be able to programme their workstations to process different types of samples requiring also different treatments during 24-h working days.

## Introduction

A chemical analysis is generally accomplished on only a small fraction of the material/population of interest. Only in some exceptionally rare cases are the specimens tested and the population of concern identical. Sampling is a necessary preliminary step practically in all analytical procedures. It is defined as the operation of acquiring an unbiased representative fraction (sample) from the entire population of material to be analyzed. The operation should provide a valid sample with minimum effort and cost commensurate with the precision required. The sampling step of the overall analytical scheme is of paramount importance and needs to be given considerable attention. The quality and utility of analytical data will not be better than the care exercised in sampling and depends critically on the validity of the sample and the adequacy of the sampling strategy. This article will briefly review the general statistical theory concerning various sampling

strategies as well as some refined theories modeling the heterogeneity pattern of the material to be analyzed and the sampling errors for bulk materials.

## General Considerations and Sampling Strategies

### Random Sampling

For random sampling, samples are simply taken at random from the whole population of the material. The only requirement of such a random sampling process is that samples are drawn in a way that all parts of the population have the same chance of being sampled. This can be done by means of a table of random numbers or by means of a computer program that produces pseudorandom numbers. If each of the  $n_s$  samples taken is analyzed  $n_a$  times, the overall variance of the whole procedure,  $\sigma_o^2$ , is

$$\sigma_o^2 = \frac{\sigma_s^2}{n_s} + \frac{\sigma_a^2}{n_s n_a} \quad [1]$$

where  $\sigma_s^2$  and  $\sigma_a^2$  are the variances of the material sampled and the analysis, respectively. Equation [1] can be used for the random sampling design. Assume that

$$\sigma_a^2 = \alpha \sigma_s^2 \quad [2]$$

## Introduction

A chemical analysis is generally accomplished on only a small fraction of the material/population of interest. Only in some exceptionally rare cases are the specimens tested and the population of concern identical. Sampling is a necessary preliminary step practically in all analytical procedures. It is defined as the operation of acquiring an unbiased representative fraction (sample) from the entire population of material to be analyzed. The operation should provide a valid sample with minimum effort and cost commensurate with the precision required. The sampling step of the overall analytical scheme is of paramount importance and needs to be given considerable attention. The quality and utility of analytical data will not be better than the care exercised in sampling and depends critically on the validity of the sample and the adequacy of the sampling strategy. This article will briefly review the general statistical theory concerning various sampling

strategies as well as some refined theories modeling the heterogeneity pattern of the material to be analyzed and the sampling errors for bulk materials.

## General Considerations and Sampling Strategies

### Random Sampling

For random sampling, samples are simply taken at random from the whole population of the material. The only requirement of such a random sampling process is that samples are drawn in a way that all parts of the population have the same chance of being sampled. This can be done by means of a table of random numbers or by means of a computer program that produces pseudorandom numbers. If each of the  $n_s$  samples taken is analyzed  $n_a$  times, the overall variance of the whole procedure,  $\sigma_o^2$ , is

$$\sigma_o^2 = \frac{\sigma_s^2}{n_s} + \frac{\sigma_a^2}{n_s n_a} \quad [1]$$

where  $\sigma_s^2$  and  $\sigma_a^2$  are the variances of the material sampled and the analysis, respectively. Equation [1] can be used for the random sampling design. Assume that

$$\sigma_a^2 = \alpha \sigma_s^2 \quad [2]$$

Equation [1] can be rewritten as

$$\sigma_o^2 = \frac{\sigma_s^2}{n_s} + \frac{\alpha}{n_a} \left( \frac{\sigma_s^2}{n_s} \right) \quad [3]$$

From eqn [3], one can draw the following conclusions:

1. For given  $\alpha$ ,  $n_s$ , and  $n_a$ , the overall variance increases with increasing  $\sigma_s^2$ .
2. For given total number of analytical determinations,  $n_a n_s$ , and without cost-benefit considerations, the random sampling process should be planned with a reasonably large  $n_s$ . For example, six random samples with duplicate analyses would give better results than four samples each analyzed three times.
3. The overall variance is a linear function of  $\alpha$ . When  $\alpha$  is very small, that is, the variance of analytical determination is substantially smaller than the variance of the material sampled, the term  $\alpha/n_a(\sigma_s^2/n_s)$  would be negligible compared to the term  $\sigma_s^2/n_s$ . In such cases, there is little point in attempting to reduce the variance of analytical determination,  $\sigma_a^2$ . As a rule of thumb, when  $\sigma_a^2$  is one-third of or less than  $\sigma_s^2$ , further reduction of the analytical error by switching to expensive and sophisticated analytical procedures does not make much sense.

Practically, eqn [1] should be solved in combination with a cost-benefit analysis. Assume that the costs for sampling and analytical determinations are  $C_s$  and  $C_a$ , respectively, then the total cost,  $C$ , of the random sampling for  $n_s$  samples per  $n_a$  analyses should be:

$$C = n_s C_s + n_s n_a C_a \quad [4]$$

Combination of eqns [1] and [4] with subsequent differentiation would give the number of analytical determinations that should be carried out on each sample to minimize the total cost for fixed variances:

$$n_a = \frac{\sigma_a}{\sigma_s} \left( \frac{C_s}{C_a} \right)^{1/2} \quad [5]$$

The number of samples needed is

$$n_s = \frac{\sigma_s^2 + (\sigma_a^2/n_a)}{\sigma_o^2} \quad [6]$$

### Systematic Sampling

In systematic sampling, samples are collected on the basis of a given geometric or time pattern, for instance, at some regular intervals of spatial location or time. Sometimes the segregation of population

occurs and is known *a priori*, sampling should cover all parts of population more or less evenly, such as different depth in a tank of liquids. In these cases stratified sampling (*vide infra*) should really be used and systematic sampling would provide a quicker, more direct way as a compromise. The error and cost-benefit analysis of systematic sampling are similar to those of random sampling.

### Stratified Sampling

In stratified sampling the population to be examined is first divided into a number of portions called strata, followed by random sampling within each stratum. The overall variance,  $\sigma_o^2$ , is

$$\sigma_o^2 = \frac{\sigma_b^2}{n_b} + \frac{\sigma_s^2}{n_b n_s} + \frac{\sigma_a^2}{n_b n_s n_a} \quad [7]$$

Here  $n_b$  is the number of strata sampled,  $\sigma_b^2$  is the variance between strata,  $n_s$  is the number of samples per stratum, and  $\sigma_s^2$  is the variance within each stratum. The stratified sampling gives results as precise as random sampling when the whole population is homogeneous. When variance among strata is remarkable compared with variance within each stratum, sampling by stratified procedure is always preferred. Equation [7] has no unique solution for  $n_b$ ,  $n_s$ , and  $n_a$ . Compromises will be necessary, taking into consideration the relative cost of selecting a stratum  $C_b$ , sampling cost within each stratum  $C_s$ , and the cost of analytical determination  $C_a$ . The total cost of the process,  $C$ , is

$$C = n_b C_b + n_b n_s C_s + n_b n_s n_a C_a \quad [8]$$

When the variances are fixed, the optimum values of  $n_b$ ,  $n_s$ , and  $n_a$ , which minimize the total cost  $C$ , are

$$n_b = \sigma_b (\sigma_b C_b^{1/2} + \sigma_s C_s^{1/2} + \sigma_a C_a^{1/2}) / (\sigma_o C_b^{1/2}) \quad [9]$$

$$n_s = \frac{\sigma_s}{\sigma_b} \left( \frac{C_b}{C_s} \right)^{1/2} \quad [9a]$$

$$n_a = \frac{\sigma_a}{\sigma_s} \left( \frac{C_s}{C_a} \right)^{1/2} \quad [9b]$$

### Representative Sampling

The representative sampling as practiced in analytical chemistry is a stratified sampling that can provide an unbiased estimate of the population mean for the target component. For the case when the strata in stratified sampling are different in size and

in variance, in order to obtain an unbiased estimated population mean with minimum variance, the number of samples drawn from stratum  $k$ ,  $n_{sk}$ , should be taken in relation to its size,  $w_k$ , and standard deviation,  $(\sigma_s)_k$ :

$$\frac{n_{sk}}{n} = \frac{w_k(\sigma_s)_k}{\sum_k^{n_b} w_k(\sigma_s)_k} \quad [10]$$

For the case when all strata have the same standard deviations, eqn [10] simplifies to

$$\frac{n_{sk}}{n} = \frac{w_k}{\sum_k^{n_b} w_k} \quad [11]$$

Equation [11] states that the number of samples taken from different strata should be properly related to the size of the strata. Obviously, such samples cannot be taken by random sampling. Many analytical technical protocols prescribe the procedures for obtaining samples for specific purposes. These samples are considered by authoritative organizations as representative of specific objects. Such representative sampling procedures are usually designed with consideration of eqns [10] and [11]. Obviously, the estimate of population mean,  $\bar{x}$ , calculated from the stratum means,  $\bar{x}_k$ , weighted in relation to the size of strata will be an unbiased one 'representing' the given population:

$$\bar{x} = \frac{\sum_k^{n_b} w_k \bar{x}_k}{\sum_k^{n_b} w_k(\sigma_s)_k} \quad [12]$$

Sometimes the only information required from the analytical process is the average composition of the population. According to the principle of representative sampling, a composite sample can be prepared by some approved standardized protocols to provide the necessary information.

### Separation and Estimation of Variances Associated with Stratification, Sampling, and Analysis

Equation [7] contains variances  $\sigma_b^2$ ,  $\sigma_s^2$ , and  $\sigma_a^2$ , which are unknown. When analytical determinations are carried out for different strata, these variances will contribute to the overall variance  $\sigma_o^2$  simultaneously. Suppose again that for the  $n_b$  strata sampled,  $n_s$  samples are taken per stratum and each sample is analyzed  $n_a$  times. Let  $x_{kji}$  be the analytical result of the target component for  $i$ th determination of  $j$ th sample taken from the  $k$ th stratum. For each sample  $j$  from stratum  $k$  the mean of  $n_a$  determinations is  $\bar{x}_{kj}$ . One has  $n_b n_s n_a$  individual results. The estimate of  $\sigma_a^2$  or  $s_a^2$  can be obtained with  $n_b n_s (n_a - 1)$  degrees of

freedom:

$$V_a = \frac{\sum_k^{n_b} \sum_j^{n_s} \sum_i^{n_a} (x_{kji} - \bar{x}_{kj})^2}{n_b n_s (n_a - 1)} \quad [13]$$

$$V_a = S_a^2 \quad [14]$$

For  $k$ th stratum, one can write for  $n_s$  sample averages ( $\bar{x}_{kj}$ ,  $j = 1, \dots, n_s$ ):

$$V_s = \frac{\sum_k^{n_b} \sum_j^{n_s} (\bar{x}_{kj} - \bar{x}_k)^2}{n_b n_s (n_s - 1)} \quad [15]$$

where  $\bar{x}_k$  is the mean for stratum  $k$ .  $V_s$  is related with the estimates of  $\sigma_a^2$  and  $\sigma_s^2$ , which are  $s_a^2$  and  $s_s^2$ , respectively:

$$n_a V_s = n_a S_s^2 + S_a^2 \quad [16]$$

For  $n_b$  stratum averages,  $\bar{x}_k$ ,  $k = 1, \dots, n_b$ , and the grand average  $\bar{x}$ , one can write:

$$V_b = \frac{\sum_k^{n_b} (\bar{x}_k - \bar{x})^2}{n_b - 1} \quad [17]$$

$V_b$  is related with  $s_a^2$  and  $s_s^2$  together with the estimate of  $\sigma_b^2$  or  $s_b^2$ :

$$n_s n_a V_b = n_s n_a s_b^2 + n_a s_s^2 + s_a^2 \quad [18]$$

From eqns [14], [16], and [18], one can obtain the estimates of the variances associated with stratification, sampling, and analysis.

### Estimation of Minimum Number of Samples Using *t*-Statistics

So far the appropriate number of samples has been estimated in terms of true variances of the material sampled and the analysis. Only the estimates of the values of these true variances can be obtained from the limited number of samples and analyses. It is actually impractical to also obtain the true value of the population mean,  $\mu$ , from a limited number of analyses. The measured mean,  $\bar{x}$ , calculated from  $n$  times of analysis is close to the true value of  $\mu$  within certain confidence limits:

$$\mu = \bar{x} \pm \frac{t s_o}{\sqrt{n}} \quad [19]$$

where  $s_o$  is the estimate of overall standard deviation  $\sigma_o$ . Student's  $t$  is taken for a particular confidence level and  $(n - 1)$  degrees of freedom. The squared difference between  $\mu$  and  $\bar{x}$ ,  $(\mu - \bar{x})^2$ , is a measure of the overall error,  $e_o^2$ . With an analytical process including the sampling steps having an overall

standard deviation of  $s_o$ , the minimum number of analyses necessary to confine the overall error within  $\pm e_o$  is

$$n = \frac{t^2 s_o^2}{e_o^2} \quad [20]$$

In order to find out  $n$ , one needs the value of  $t$  for a given confidence level and  $(n-1)$  degrees of freedom. Since  $n$  is not yet known, the value of  $t$  for  $n = \infty$  and given confidence level can be used for calculating an approximate  $n$ .

By using the value of  $t$  for this approximate  $n$ , one can recalculate a more precise  $n$ . This iterative process is repeated until  $n$  converges to a constant value. In random sampling the number of analyses is  $n_a n_s$ . If the estimated standard deviation of the analytical measurement process,  $s_a$ , is negligible, and consequently the error of analytical measurement,  $e_a$ , is also negligible, one can write for the number of samples that must be taken in the sampling process,  $n_s$ , as

$$n_s = \frac{t^2 s_s^2}{e_s^2} \quad [21]$$

Equation [21] was derived for the case when the sample is very small in comparison with the whole population. For the case when the sample is a substantial part of the population, a so-called 'finite population correction' factor,  $(1 - n/N)^{1/2}$ , should be introduced. Here,  $N$  is the total number of samples contained in the whole population, the second term of the right-hand side of eqn [19] should be multiplied by this factor. Consequently, eqn [21] takes the following form:

$$n_s = \frac{t^2 s_o^2 N}{e_s^2 N + t^2 s_s^2} \quad [22]$$

Evidently, the finite population correction should be taken into consideration only for relatively small, finite population cases. It can be neglected whenever  $N$  is sufficiently large, as then  $(1 - n/N)^{1/2}$  approaches unity. Equations [21] and [22] can be used for estimating the number of samples necessary to confine the sampling error within  $\pm e_s$  with the confidence level chosen for the  $t$  value (95%, for example), provided the estimated variance within the sample unit is  $s_s^2$ .

Introduction of the  $t$  statistics and the concept of confidence limits makes the estimation of the number of samples needed for a specific purpose more realistic. Some expressions described in the previous sections should be modified when the true variances are substituted for their estimates and when the

confidence limits of the conclusions drawn from the corresponding calculations are considered. Equation [1] for random sampling, for example, can be rewritten as

$$e^2 = \frac{t^2 s_s^2}{n_s} + \frac{t^2 s_a^2}{n_s n_a} \quad [23]$$

This modified expression states that if one takes the  $t$  value for an appropriate degree of freedom and a confidence level of, say, 95%, one can be 95% confident that the overall error of the whole analytical process will not be greater than  $e^2$ . Similarly, expression [6] can be rewritten as

$$n_s = \frac{t^2 (s_s^2 + s_a^2/n_a)}{e^2} \quad [24]$$

## Sampling Constants

### Ingamells' Sampling Constant

Ingamells defined a sampling constant,  $K_s$ , for characterization of the homogeneity of a well-mixed laboratory sample. The relative standard deviation,  $R$ , expressed in per cent

$$R = 100 \times s_s / \bar{x} \quad [25]$$

is inversely dependent on the mass ( $w$ ) of the sample analyzed:

$$R^2 = \frac{K_s}{w} \quad [26]$$

The coefficient of proportion,  $K_s$ , which has the units of mass, is called the sampling constant. When  $w = K_s$ ,  $R = 1\%$ . As this expression contains  $R$ , which is related with the estimated value of standard deviation, one can imagine from the reasoning of the previous section that in eqn [26] there is an implicit  $t$  that equals unity. This is the  $t$  value for degree of freedom of infinity and confidence level  $\alpha$  of 0.3174. So the sampling constant is just the sample weight necessary to ensure a relative sampling error  $R$  of 1% with 68% ( $1 - 0.3174 = 0.6826$ ) confidence in a single determination:

$$K_s = R^2 w \quad [26a]$$

The square root of the  $K_s$  is numerically equal to the relative standard deviation of a set of results obtained from 1 g samples by a precise analytical method with negligible  $\sigma_a^2$ . This is one of the experimental approaches for determining  $K_s$ . Actually, one can estimate  $R$  for given  $w$  by repeated precise analysis using expression [25]. Once  $K_s$  is evaluated for the sample population, the minimum weight,  $w$ , needed for a maximum acceptable relative standard

deviation for this population can be estimated. This is an experimental method for determination of the minimum sample weight needed in the sampling process. It is possible to calculate this sample weight or the sampling constant itself by using some sampling theories (*vide infra*). If the population sampled is a well-mixed one, expression [26] holds fairly well. For extremely heterogeneous materials that are segregated or stratified, the value of  $K_s$  calculated for different batches would not be constant and might vary with  $w$ . This is one way for judging the degree of mixing of the population. For a segregated population, an additional segregation constant should be introduced.

### Visman's Sampling Constants

Visman developed the theory of sampling taking into consideration the effect of segregation. The experimentally estimated variance  $s_s^2$  is related to two sampling constants, a homogeneity constant  $A$ , which is similar to Ingamells' constant, and a segregation constant  $B$ :

$$s_s^2 = \frac{A}{wn_s} + \frac{B}{n_s} \quad [27]$$

where  $wn_s$  is the total mass of  $n_s$  samples. If the population is not segregated,  $B=0$ , one has the expression similar to eqn [26]. Considering eqn [25], one can find the relationship between Ingamells' sampling constant and Visman's homogeneity constant:

$$A = 10^{-4} \times \bar{x}^2 \times K_s \quad [28]$$

Constants  $A$  and  $B$  can be determined experimentally by collecting one series of small samples and one series of large samples. The sampling variances of these two series are estimated. The weights and variances of these two sets are used to set up two simultaneous equations of the form [27] and the values of  $A$  and  $B$  can be obtained by solving these equations. Equation [27] shows that the effect of the number of samples ( $n_s$ ) increases with the increasing value of  $B$ . A reasonably large  $n_s$  is preferred for reducing sampling variance. When  $B$  is zero, there is no segregation of the population and the number of samples does not affect the sampling variance as far as the total weight of the samples,  $wn_s$ , is fixed.

### Modeling the Heterogeneity Pattern and Sampling Errors for Bulk Materials

So far the sampling problem has been discussed from a general view by using statistical or experimental

methods. Actually, the sampling error for bulk materials is mainly caused by heterogeneities in the material under study. For a well-mixed gas or liquid, the homogeneity is of such a high degree that any small part of the whole will be really a representative sample of the population. A sample in the ordinary sense is too large and the precision of an analytical procedure is too low for the detection of the variation of composition of such homogeneous populations. The sampling problem arises when a small fraction is taken from a heterogeneous population. Naturally, modeling and statistical treatment of the heterogeneity pattern of the population to be sampled constitute the core of any sound theory of sampling from bulk materials.

### The Simplest Starting Model

Benedetti-Pichler drew an analogy between the sampling from bulk materials and counting the ratio of white and red beans in a silo containing hundreds of metric tons of a mixture of these two kinds of beans. As counting all the beans in the silo would involve years of work, one would switch to a more realistic, but less precise approach: take a sample from the silo and make the count for it. The sample size is determined by the precision desired and can be estimated by using the binomial distribution. A similar philosophy has been adopted in most modern theories for sampling from bulk materials.

Assume that the population is a mixture of density  $\rho$  of two kinds of cubic particles, A and B, of the same density. These particles are of the same size with a side of cube of  $u$ , the weight percentages of particles A and B in the population are  $w_A$  and  $w_B$ , respectively. As the simplest model, assume that only type A particles contain the sought-for component  $x$  of a weight percentage  $x_A$ . The weight percentage of the sought-for component in the whole population is  $x$ . One takes a sample of weight  $w$  from the population for chemical analysis. The sampling variance is  $\sigma_s^2$ . This model can be treated using the binomial distribution. For a binomial distributed variable, the variance  $\sigma^2$  is  $npq$ . In terms of the simplest sampling model under discussion, the number of particles ( $n$ ) in the sample is  $w/\rho u^3$ , the probability ( $p$ ) for taking at random a particle A is  $w_A\%$ , the probability ( $q$ ) for taking a particle B is  $w_B\%$  or  $(100 - w_A)\%$ . One can write for the  $\sigma_s^2$  expressed in numbers of particles:

$$\sigma_{s(\text{particle})}^2 = \frac{w \times w_A \times (100 - w_A)}{\rho u^3 \times 1000} \quad [29]$$

In terms of the percentage of the sought-for component,  $\sigma_{s(\text{particle})}$  should be divided by the number

of particles:

$$\sigma_s = \frac{\sigma_{s(\text{particle})}}{w/\rho u^3} \times 10^2 \quad [30]$$

The simplest case is that particle A is the pure sought-for component, e.g.,  $w_A = x$ , then

$$\sigma_s^2 = \frac{\rho u^3}{w} x(100 - x) \quad [31]$$

Equation [31] can be used to evaluate the sampling error for given sample weight or, conversely, estimate the minimum sample weight necessary for obtaining the desired sampling precision. This expression is based on an oversimplified model. For practical uses the model should be refined to make it closer to the analytical realities.

### Extension of the Model to More Realistic Cases

In the above model type A and B particles were assumed to have the same density. If type B particles have a density of  $\rho_B$  different from that of type A particles,  $\rho_A$ , and if not only type A particles contain  $x$ , but type B particles also contain the sought-for component and the weight percentage is  $x_B$ , then some corrections should be introduced to the simplest model:

$$\sigma_s^2 = \frac{\rho_A \rho_B}{\rho} \times \frac{u^3}{w} \times w_A(100 - w_A) \left( \frac{x_A - x_B}{100} \right)^2 \quad [32]$$

One notices that instead of the uniform density  $\rho$  of the whole population, the densities of particles A and B,  $\rho_A$  and  $\rho_B$ , respectively, are taken into consideration by replacing  $\rho$  with  $\rho_A \rho_B / \rho$ . The squared term  $(x_A - x_B/100)^2$  accounts for the difference in composition of two kinds of particles. It is obvious that the greater the difference between  $x_A$  and  $x_B$ , which is a measure of heterogeneity of the population, the greater the sampling variance.

Ingamells' sampling constant can be evaluated by comparing expressions [31] and [32] with eqns [30], [25]–[26a]. Ingamells himself gave several theoretical expressions for  $K_s$ , one was in the following form:

$$K_s = R^2 w \frac{(x_B \rho_B - x_A \rho_A)^2 (x_B - x)(x - x_A) u^3}{\rho_B (x_B - x)(x_B - x_A) + \rho_A (x - x_A)(x_B - x_A)} \times \frac{10^{18}}{x^2} \quad [33]$$

The expressions for binary mixtures can be extended to the case of 'more than two components'. The later case is complicated by the fact that since the sought-for component may be present in several types of particles, its variance will depend on the variances

and covariances of these various particles. The distribution of the component in a population has certain unusual statistical features in the application of bi- and multinomial statistics. For a mixture containing  $m$  types of particles of densities  $\rho_i$ , weight percentage in the population  $w_i$ , and weight percentage of  $x$  in the particle  $x_i$ , the expression for  $\sigma_s^2$  is given by Wilson's equation:

$$\sigma_s^2 = \frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m \left( \frac{\Delta x_i \rho_i - \Delta x_j \rho_j}{100} \right)^2 \times \left( \frac{w_i w_j}{\rho_i \rho_j} \right) \times \left( \frac{u^3 \rho}{w} \right) \quad [34]$$

Here  $i$  and  $j$  refer to any two types of particles present out of  $m$  types,  $\Delta x_i$  is the difference between  $x_i$  and overall  $x$  content in the population. It is assumed that all the particles in the population are of uniform volume. When the particle densities differ greatly, eqn [34] is valid only if  $s_s$  is not too large.

### Introduction of Particle Property Factors: Gy's Theory

Gy's classical theory is a comprehensive theory for the sampling from heterogeneous materials developed on the basis of studying the sampling of granular materials. The simplest model expressed by eqn [31] can be modified according to Gy's sampling theory:

$$\sigma_s^2 = \rho u_3 x(100 - x) \left( \frac{1}{w} - \frac{1}{W} \right) f g l \quad [35]$$

In this expression, the term  $1/w$  of eqn [31] is replaced by  $(1/w - 1/W)$ . This replacement reflects the effect of the total mass of the bulk material,  $W$ , on the sampling variance. The sampling error decreases with increasing  $w$  and decreasing  $W$ . When  $w$  comes nearer to  $W$ , the sampling error approaches zero. When the size of population is much larger than the sample size,  $(1/w - 1/W)$  approaches  $1/w$ , the term used in eqn [31]. In expression [35], some additional parameters  $f$ ,  $g$ , and  $l$  are introduced. These parameters take into account the effects of the particle properties.

**Particle shape factor ( $f$ )** In derivation of eqn [31], all particles were assumed to be cubes of volume of  $u^3$ . In reality, particles may be different in shape. The factor  $f$  takes into account the deviation of the particle shape from cubicity. It is actually the ratio of the average volume of the real particles having a maximum linear dimension equal to the sieve size to the volume of the cube passing the same sieve. For the idealized case of eqn [31],  $f=1$ . If all particles are spheres of diameter  $u$ ,  $f=0.524$ . For most

populations  $f$  can be assumed to be 0.5, this is a better approximation than expression [31], which assumes  $f=1$ . For bulk materials with special shape such as particulate gold, the value of  $f$  might be as low as 0.2.

**Particle-size distribution factor ( $g$ )** For the simplest model of expression [31], all particles were assumed to have the same size. For a real mixture of particles the distribution of the size of particles should be considered and the factor  $g$ , the ratio of the upper size limit to the lower size limit, is introduced. For the idealized case of expression [31],  $g=1$ . When the size range is relatively large, such as the case when the bulk material is crushed and pulverized with no size classification, a value for  $g$  of 0.25 is recommended. For medium or small size ranges, the value for  $g$  may be taken as 0.50 or 0.75, respectively.

**Liberation factor ( $l$ )** For the simplest model it was assumed that the bulk material consisted of two kinds of particles, A and B. For eqn [31], it was even assumed that  $w_A=x$ . In real situations, it is possible that lumps of bulk material contain both kinds of particles. When the material is crushed, the particles that contain the sought-for component are liberated from the lump. This liberation process is taken into consideration by introducing the liberation factor,  $l$ , which is defined as

$$l = \left( \frac{u_1}{u_2} \right)^{1/2} \quad [36]$$

Here  $u_1$  is the size of the average grains of sought-for component in the lump and  $u_2$  is the size of the largest lump particle in the material. When  $u_2 \leq u_1$ ,  $l=1$ , no liberation process should be considered. Parameters for evaluation of the factor  $l$  may be estimated by microscopic examination and sieve tests.

**Composition factor ( $c$ )** Besides  $(1/w - 1/W)$ ,  $f$ ,  $g$ , and  $l$ , one can define a factor  $c$ , which is the contribution of the variation of the particle composition. Considering that the overall density  $\rho$  is a weighted average of densities of two kinds of particles,  $\rho_A$  and  $\rho_B$ , e.g.,

$$\rho = \frac{x}{100} \rho_A + \frac{(100-x)}{100} \rho_B \quad [37]$$

The factor  $c$  is defined as:

$$c = x(100-x) \left[ \frac{x}{100} \rho_A + \frac{(100-x)}{100} \rho_B \right] \quad [38]$$

Gy's sampling theory can be expressed by a very simple equation:

$$\sigma_s^2 = u^3 \left( \frac{1}{w} - \frac{1}{W} \right) c f g l \quad [39]$$

## Introduction

The purpose of sampling is to estimate the amount or properties of bulk material. Samples are taken

from a continuous stream, an individual lot, or a sequence of lots. A sampling standard is thus necessary because of the potential for numerous sources of variations within the bulk material, resulting from the sampling procedure employed, the preparation of composite samples, and measuring errors.

Sampling is a complex procedure for characterization of bulk material using individual

samples. The individual steps in this process are as follows:

1. formulation of the terms of reference for the purpose of the sampling,
2. specification of the selection criteria (quality characteristics) for assessing the bulk material,
3. creation of a model of temporal and spatial variability of the properties of the assessed bulk material (quality variation), from which the sampling scheme follows,
4. selection of suitable instruments for taking individual samples and the operating requirements for sampling (the sampling procedure), and
5. requirements and instructions related to the methods and criteria for dividing the sample (sample preparation procedure).

The relationships and basic principles connected with sampling are given in **Figure 1**. The bulk material may consist of strata (mutually exclusive and exhaustive subpopulations considered to be more homogeneous with respect to the characteristics investigated than the total population) or of samples (subset of a specified population made up of one or more sampling units).

Sampling is undoubtedly the most important part of an analytical procedure; its importance is fully manifested in the concept of analytical uncertainty, and it fundamentally affects the magnitude of the expanded uncertainty of the method. Sampling

involves a well-defined method based on the experimentally observed properties of the evaluated bulk material. Standard processes offer various recommended sampling procedures, whose final form and scope form the subject of customer–contractor agreements and contracts. The results of sampling that is not a part of the quality system constitute only expensive information noise, which should be suppressed to the maximum extent possible.

Sampling is employed to ensure that a representative sample is obtained. The purpose of the sampling procedure is to ensure the expected probability of sampling, i.e., to fulfill the requirement that all the parts of the bulk material have the same probability that they will be sampled and that they appear in the sample for testing. Any deviation from this basic requirement may lead to unacceptable bias and the creation of a sample that is not representative.

There are various sampling procedures:

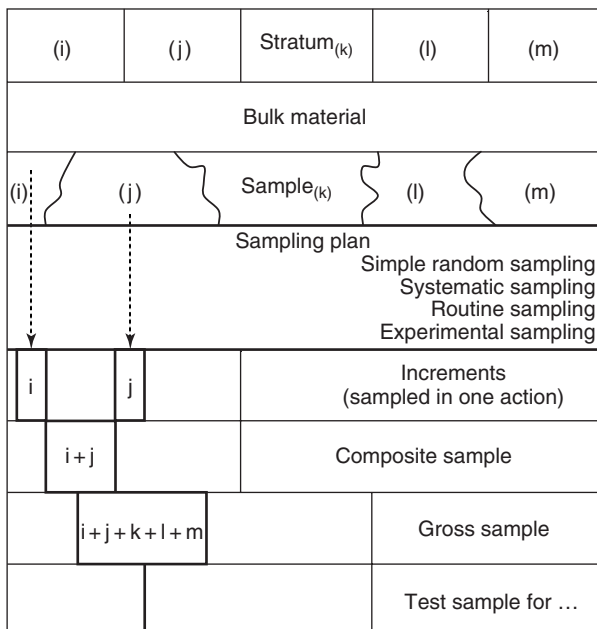

1. *Simple random sampling* – sampling where a sample of  $n$  sampling units is taken from a population in such a way that all combinations of  $n$  sampling units have the same probability of being taken.
2. *Systematic sampling* – sampling according to a methodical plan.
3. *Routine sampling* – sampling for commercial purposes carried out by the stipulated procedures in the specific international standard in order to determine the average quality of the lot.
4. *Experimental sampling* – nonroutine sampling where special-purpose experimental design is employed to investigate sources of variance and/or sampling bias.

In the framework of all the sampling procedures, an ‘increment’ sample is taken; the complex ‘composite’ and ‘gross’ samples are created from these increments, and from this, the ‘test’ sample is taken for a certain type of testing or analysis.

Technical standard regulations, including sampling standards, do not have legal force by law. Standard regulations are generally valid recommendations that may govern contract relations. The use of issued standards is voluntary, and their undoubted authority follows from their high technical level.

The scope and difficulties entailed in sampling, and the problem of preparing a general, unique sampling procedure for all potential cases have been discussed in the above. For a specific case of sampling, the sampling procedures are the subject of a contract agreement between the contractor and the customer.

National standards generally refer to international standards by stating that ‘This standard is the

**Figure 1** Basic terms in sampling of materials.

national version of International Standard ISO XXXXX-X:YYYY. International Standard ISO XXXXX-X:YYYY has the status of a 'National' Standard'. Under these conditions, mutual comparability of the recommended principles and procedures is achieved and thus contract regulation in exchange of goods and services is easier and less ambiguous.

A correct sampling scheme, i.e., a system of procedures and techniques specified by sampling plans, must facilitate determination of errors and individual steps in sampling and variations in the quality of the bulk material itself.

## Creation of a Sampling Scheme

The process of sampling is usually divided into three steps, where each step has its own variance:

1. the process of taking increments, with the variance caused during increment sampling,  $s_s^2$ ;
2. the process of sample preparation, with variance caused during test sample preparation,  $s_p^2$ ; and
3. the process of measurement, with variance characterizing the precision of the measuring method (analytical method) used,  $s_M^2$ .

The overall variability of the monitored characteristic for  $z$  individual samples and  $n_M$  repeated analyses is equal to  $s_T^2$  and it is given by

$$s_T^2 = \frac{s_s^2}{n} + s_p^2 + \frac{s_M^2}{n_M} \quad [1]$$

The whole of the bulk material is generally heterogeneous, and its mass is distributed in three-dimensional space. Consequently, in creating each sampling scheme, it is necessary, in the first stage itself, to determine the heterogeneity of the material in the framework of the total mass and its distribution in space.

The probability of exact determination of the quality characteristic, characterized by the variance  $s_T^2$ , increases with the amount of analyzed material (e.g., mass, volume, time, number of items). The ratio of the amount of analyzed material,  $m$ , to the total amount of material,  $m_T$ , is characterized as the sampling efficiency,  $\Phi$ :

$$\Phi = \frac{m}{m_T} \quad [2]$$

Here, the amount of analyzed material,  $m$ , can be expressed as the product of the number of samples,  $z$ , and their mass,  $m_i$ :

$$m = zm_i \quad [3]$$

$$s_T^2 = \left(1 - \frac{nm_i}{m_T}\right) \frac{s_s^2}{m} \quad [4]$$

where the heterogeneity of the material,  $s_s^2$ , is caused by two contributions:

$$s_s^2 = s_{s1}^2 + s_{s2}^2 \quad [5]$$

The first term of the right-hand side of eqn [5] can be designated as the short-term quality variation and is a consequence of the different compositions of the individual samples taken at successive, shortest possible intervals (20–40 individual samples). This short-term quality variation corresponds to the variance  $s_{s1}^2$ .

The second contribution is designated as the long-term quality variation and is a consequence of temporal and spatial changes during sampling. This long-term quality variation corresponds to the variance  $s_{s2}^2$ .

The results of repeated analysis of individual samples are given in the form of a variogram (the variogram is a plot of the variance as a function of the intervals between the original data values; the interval between consecutive data values is called lag one, that between every second data value is called lag two, etc.). It enables determination of the regression coefficients  $A$  (which is a function of  $s_{s1}^2$ ) and  $B$  (which is a function of  $s_{s2}^2$ ) and the variance of the evaluated material as a consequence of the segregation and aggregation,  $s_G^2$ , which is a function of the particle size,  $d$ . These quantities are further used in eqn [6] for the determination of the mass of the increment,  $m_i$ , and the number of increments,  $z$ , for sampling of bulk material with an overall mass  $m_T$ . It holds that

$$s_s^2 = \frac{Ad^3}{zm_i} + \frac{s_G^2}{z} + \frac{Bm_T}{6z^2} \quad [6]$$

These relationships indicate the broad variability of the sampling scheme. Economic aspects are the main criteria in decision making in selecting a scheme, both from the standpoint of the price of the sampled material (for expensive materials,  $m_i$  will be small and  $z$  large) or the price of the analysis (for expensive analyses,  $z$  will be small and the mass of the increments,  $m_i$ , will be large). It is also apparent that mechanical sampling leads to a large number of samples,  $z$ , and is especially suitable for bulk materials with a large overall amount,  $m_T$ .

## Experimental Sampling

Like the processes of sampling, the sample treatment and measurement are experimental procedures, and each of them is accompanied by an experimental error, which should have a random distribution, its magnitude should not significantly affect sampling. However, it may occur that the sampling scheme,

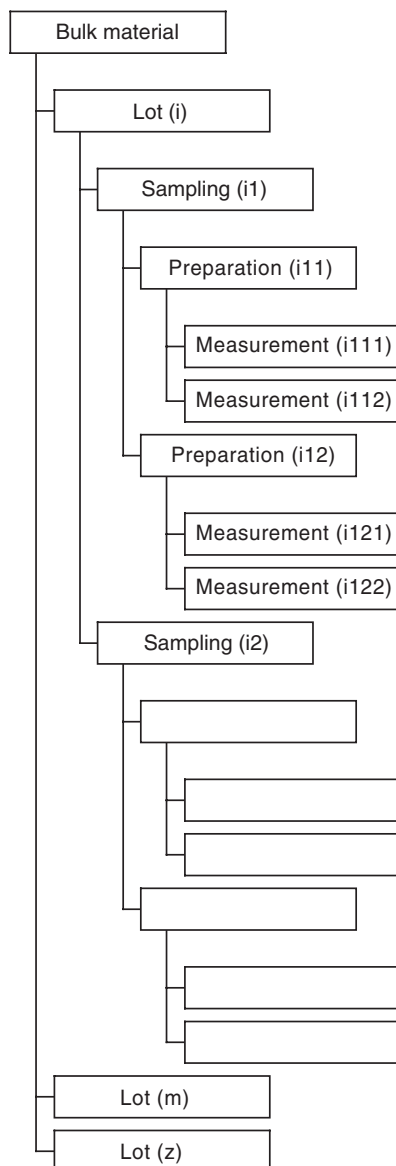

sampling procedure, or sample treatment employed will be accompanied by systematic errors. Such errors can be discovered and their magnitude can be determined only by comparative procedures, which form the basis of experimental sampling. The procedures of experimental sampling are generally based on the factorial design of the experiment.

Determination of the individual sources of errors in the sampling and heterogeneity of the material is made possible through creation of a suitable sampling scheme according to **Figure 2** and should precede systematic sampling.

The variability of the individual phases of sampling can be calculated on the basis of an experiment carried out according to **Figure 2**. **Table 1**

indicates the magnitude of variances in the individual phases. The values of variance determined in this procedure are then used for calculating the required sampling efficiency (eqn [4]) and for the required number of increments (eqn [6]).

The above principles are generally valid for materials in all states and for all applications. *A priori* simplification and the use of unverified values for the scattering variables for individual stages of sampling leads not only to erroneous determination of the magnitude of the quality characteristic but also to limited usefulness of the values determined and economic waste. As the creation of a sampling scheme is a key task, it is advisable to consult a professional for this step and ensure that the scheme is approved in the framework of contractor–customer relations.

**Figure 2** Full factorial design for experimental sampling.

## The Reason for Sampling

The creation of a sampling scheme always has a predefined purpose. For a given material, the sampling scheme will differ for the case of determination of the mean value of the quality characteristic of the material at the time of delivery (e.g., the water content in a delivery of coal) and for regulation of the quality characteristic of the material (e.g., the water content in coal used for coke production).

A large number of parallel standard regulations with similar internal structure exist for sampling of production processes and products. The politically highly topical area of the environment can serve as an example. Thus, one can find a standard for taking samples for measuring pollution levels in air, for stratified sampling for evaluating the quality of ambient air, for sampling for automatic determination of the mass concentration of gaseous components, and for the determination of the components of stationary emission sources, e.g., determination of the mass concentrations of PCDD/PCDF, HCl, sulfur dioxide, sulfur oxide, and sulfuric acid and the total content of sulfur oxides, ammonia, hydrogen sulfide, carbon disulfide, nitrogen oxide, fluorine,

**Table 1** Analysis of variances of sampling steps carried out in accordance with **Figure 2** for bulk material comprising  $z$  lots

Step	Source of variability	Degrees of freedom	Expected variance
1	Between lots	$z - 1$	$s_L^2 + s_S^2 + s_P^2 + s_M^2$
2	Sampling within lot	$z$	$s_S^2 + s_P^2 + s_M^2$
3	Sample preparation within sampling	$2z$	$s_P^2 + s_M^2$
4	Measurement within sample preparation	$4z$	$s_M^2$

etc. A similar situation exists for sampling of water and particulate matter.

It is obvious that the principles of the sampling scheme must be similar for all the above examples. The numerous one-purpose standards create the impression of separate, special sampling methods rather than a joint, global approach. In addition, a narrowly defined standardized approach can ignore the mutual interaction of the individual components of the bulk material and can thus lead to undesirable biased evaluation of the quality characteristic in question.

All sampling plans have a specified number of samples, sampling sites, type of sampling, and the necessary technical equipment and also describe the means of preserving the sample for subsequent analysis. However, specification of the site for taking individual increments requires a procedure that will differ from case to case. Knowledge of the properties of the material and its behavior during deposition is very useful in creating a sampling plan. When carrying out the sampling, a sampling protocol is filled out; this usually has prescribed information that must be entered by the person carrying out the sampling. Under these conditions, the sampling conditions are documented, and feedback to the description of the monitored quality characteristic of the bulk material is facilitated.

## Gas-Phase Sampling

The amount of component  $i$  in the gas phase is given by its partial pressure  $p_i$ , which is a function of the properties of the component monitored and the properties of other, simultaneously present substances and also of the ambient temperature and pressure. The composition of a gas phase is characterized by great complexity (all the chemical substances have the final vapor pressure value regardless of their polarity), instability (slow reactions take place between oxidizing and reducing substances that are simultaneously present), and low concentration levels (frequently below the detection limit in the *in situ* state). In addition to gases, the gas phase also contains suspended particulate matter and solid dust particles.

Ambient air pollution is understood to consist in human activity, during which one or more pollutants are introduced into the air. The pollution limit value is the highest permissible level of pollution of the air expressed in mass units per unit volume at normal temperature and pressure. The ambient air is most frequently sampled using methods of automatic continuous sampling, carried out by drawing the air directly into the analyzer or through a filter for analysis of dust and particulate matter (EN 12341:2000 *Air*

*Quality – Determination of the PM<sub>10</sub> Fraction of Suspended Particulate Matter*). In discontinuous sampling, sampling bottles and large-volume plastic sacks can be used.

The air quality in the working environment is generally regulated by law. The impact of dust, chemical substances, and biological factors is usually of concern. Several sampling techniques can be used here. These include analyzers for continuous sampling and measurement of the substances of interest, and also pumps and collectors utilizing adsorption, chemisorption, and dissolution to capture the substances to be determined (Table 2). These methods, in which the analytes are captured by a solid detector, are termed as solid-phase extraction methods. The method of personal passive sampling is used extensively in connection with the control of the working environment; here, the collector is located close to the nose and mouth of the worker.

When any type of collector is used, sampling leads to concentration of the individual substances and thus to an undesirable increase in the rate of reactions amongst them. In addition, when collectors are used, the homogeneous gas phase is changed into a heterogeneous environment with a certain level of chemical and surface activity.

Another problem connected with the use of collectors is their capacity to retain the sorbed substance in the collector during subsequent passage of analyzed air. There is a maximum volume of air passing through the collector for each substance in the given amount of sorbent at the given temperature and pressure, for which the sorbed substance will not be flushed out of the collector. This volume is termed  $V_{\max}$  and is specified for 1 g of sorbent and a temperature of 20°C; these values are mostly tabulated. This value can be determined experimentally using the gas chromatographic method. If the retention volume of the captured substance,  $V_R$ , in a chromatographic system with  $n$  theoretical plates is known, then

$$V_{\max} = V_R \left( 1 - \frac{2}{\sqrt{n}} \right) \quad [7]$$

These materials are usually placed in closed tubes, e.g., NIOSH (Figure 3). During sampling, the tubes are open and the sampled air is drawn through them. The volume of air drawn through the tube (of the order of liters) varies, depending on the analyte to be determined, as follows from eqn [7]. The material in the tube is divided into two parts. The first part of the detector is used to collect the sample, while the separate, connected, second part is used to control the sampling conditions (the determined analyte must not be present in the control part).

A miniature variant of the above procedures consists in placing the sorption material on fibers. These collectors are called solid-phase micro-extraction devices and are suitable for sampling smaller volumes because of the smaller amount of sorbent.

## Liquid-Phase Sampling

Water sampling is similar to all special-purpose sampling and is divided into three large groups: sampling surface waters, sampling drinking water, and sampling waste waters. Standards of the EN 25667 and ISO 5667 series are the basic ones for water sampling.

Surface water is classified as:

1. water courses – flowing water (rivers, streams, and canals);
2. water reservoirs – still water (lakes, dams, and fishponds);
3. seas and oceans; and
4. glaciers and ice fields.

Sampling of surface waters consists in taking a representative part of the water body or other component of the environment (water, fluvial deposits, sediments, biological material) to determine various, exactly defined, quality indicators. This list indicates the great variability of sampling plans.

## Sampling Drinking Water

There are very detailed standards for sampling drinking water and the national systems are based on the above-cited international standards. Control of water is carried from water taps (intended for human consumption), at the outlets of wells and reservoirs, and at the sites of filling packages and containers. Drinking water is also sampled at the input and output of water tanks and water treatment facilities, and in water mains and swimming pools.

The manner of taking samples and treating them, including preservation, depends on the analyte to be determined, and, in general, on the quality characteristics. More than 40 quality characteristics are monitored in drinking water in relation to chemical compounds and physical properties, along with the biological characteristics and toxicity tests. This variability in the monitored quality characteristics corresponds to a large number of sampling plans, a significant part of which consists in sample treatment and preservation prior to subsequent analysis. The instructions thus encompass heating the tap outlet with a flame to disinfect it, rinsing the sample bottle

with the sampled water to suppress sorption from the sample on the walls of the vessel, and warnings about not shaking and not mixing the sample to prevent release of dissolved gases, etc.

The technical equipment for taking samples is determined by the sampling site and requirements on the number of analyses and analytical methods employed. The equipment includes bottles that are either closed and then opened at the sampling site (on the surface or at a certain depth) by opening the stopper (i.e., are not flow-through) or are open and rinsed by the surrounding water and then closed at the sampling site after a certain time. While the mechanical design of the sampling bottle is not decisive for the sampling, the chemical properties of the sampling bottle can lead to alteration of the sample. Consequently, clear and dark plastic (polyethylene, polytetrafluoroethylene, polyvinyl chloride, polyethylene terephthalate) or glass (hard glass, soft glass) bottles are used.

### **Sampling Waste Waters**

Waste waters are discharged into surface waters on the basis of a permit that specifies both their volume and their degree of pollution. The practice of sampling waste waters and sludges consists in monitoring indicators of the quality of treatment, management of treatment, and monitoring of the permitted limits. The sampling plans sometimes also prescribe the number and frequency of sampling operations, sample treatment, and statistical procedures for determining the monitored quality characteristic (for waste waters, the following are monitored: chemical oxygen demand determined by using the chromate method; undissolved substances; phosphorus; ammonia; nitrites; nitrates; absorbed organic halogenated substances; mercury; and cadmium). Because of the large content of solid substances in the sample, these are removed during preliminary treatment (homogenization and filtration). In contrast to surface and drinking waters, waste waters must be analyzed within 24 h of sampling. During sampling, potential infections must be taken into account, and thus gloves should be used during sampling, the sampling equipment should not be used for sampling other materials, etc.

### **Solid-Phase Sampling**

Materials in the solid phase are characterized by the highest degree of heterogeneity and thus they are most frequently sampled. Important groups of sampled materials include especially those that affect the

environment and human health. Consequently, great emphasis is placed on sampling wastes, ash from combustion of coal, welding sands, sludges from waste water treatment plants, soils and rubble, ash from waste incinerators, fishpond sediments, etc. from the standpoint of evaluating their hazardous properties, e.g., by determining their extractability or determining pollutants in dry matter. Sampling in agriculture, of agricultural products, plants, soils and fertilizers, genetically modified organisms, etc. is not only justifiable but is necessary for analyzing food-stuffs and the entire food chain. There is no doubt about the necessity for analyzing industrial materials in the form of individual items or free-flowing materials.

All these groups of materials are characterized by a high degree of heterogeneity of the monitored characteristics with respect to the spatial and temporal changes during sampling. The sampling plans for solid materials are most complex because of these properties of the bulk material.

Solid materials are frequently sampled using methods of continuous measurement on conveyor belts, in pipeline conveyors, etc. Under these conditions, the efficiency of sampling according to eqn [2] is high and the variance,  $s_{S2}^2$ , caused by spatial and temporal changes between subsequent sampling of increment samples is small; the monitored changes in quality correspond to the heterogeneity of the material,  $s_{S1}^2$  (eqn [5]). Manual, discontinuous sampling methods have very low sampling efficiencies and lead to greater variability in the monitored quality characteristic according to eqn [4].

## SEGMENTED FLOW ANALYSIS

**S Coverly**, Norderstedt, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Segmented flow analysis (SFA) was a pioneering development in laboratory automation. It was conceived in the 1950s by Leonard Skeggs, a researcher in a clinical laboratory, and within a decade of its development, became the dominant technique in automated clinical analysis.

The rapid acceptance of SFA was due to its simplicity. Developed in the age before microprocessor control, when automating even simple procedures required complex mechanical timing and control devices, the low cost and high reliability of a flexible system employing only two moving parts – a peristaltic pump and an autosampler – was a major advance. The versatility of the system led to rapid development of methods and techniques by the manufacturer and by users in research institutions and in

industry, and by 1975 almost 8000 papers describing SFA and its applications had been published.

The use of SFA reached its peak in the mid- to late-1980s. Its use in clinical laboratories has now declined due to a move toward more highly automated systems requiring less operator involvement and with lower reagent consumption – an important factor for enzymatic reactions. In the industrial field, flow injection analysis (FIA), developed in 1975, is replacing SFA in small laboratories, but SFA is still dominant in larger laboratories, especially for determinations using long or complex procedures.

### Techniques

As shown in **Figure 1**, an SFA system consists of five basic components: sample changer, peristaltic pump, analytical manifold, detector, and data output system. The manifold contains the mixing coils, dialyzer, heater, and other components through which sample and reagents are pumped and where sample clean-up and reaction takes place. The data output

**Figure 1** Diagrammatic view of an SFA system using a dialyzer, heating bath, and colorimetric detection.

**Figure 2** Mixing coil, illustrating how liquids of differing densities are mixed by the vertical orientation of the coil.

system was originally a chart recorder, from which peak heights were measured and results were calculated by hand: recorders were later superseded by computers.

**Figure 2** illustrates the passage of liquid and air through the mixing coils in the analytical manifold. Sample and reagents are introduced through individual tubes in a continuously operating peristaltic pump. Samples follow one another from the auto-sampler; the only change in conditions within the system is thus the presence or absence of a sample. The air bubbles form barriers to longitudinal dispersion and separate the samples from each other and from the intersample wash solution. The bubbles are normally injected every 1–2 s, and the sampling time is typically 30–90 s. Each sample is thus divided into many segments, so that the small amount of carryover from one segment to the following one, which takes place via the thin film of liquid wetting the tubing surface, does not have any consequences in the segments toward the end of the sample. Indeed, the sampling time is usually selected so that at the end of the sample period there is a negligible change in concentration from one segment to the next. This results in a peak whose concentration at the end is not changing with time – a so-called ‘steady-state’ condition.

This low dispersion as samples pass through the system allows reactions lasting several minutes to take place in the flowing stream while maintaining a high sampling rate.

## Mixing and Reaction

Mixing takes place within each liquid segment due to both the internal motion of the liquid as it travels through the tubing and, where the liquids are of different densities, to gravity as segments are inverted during their passage through the mixing coils (see

**Figure 2**). Extending the length of the coil beyond that needed for complete mixing enables longer reactions to come to completion, a process that can be accelerated by heating the reaction mixture up to 95°C. Some special methods run at temperatures above 100°C, in a pressurized manifold.

A further development of mixing and reaction is ultraviolet (UV) digestion. Here a quartz coil is wrapped around a UV lamp so that the sample stream is irradiated. Depending on the type of lamp and the spectral transmission characteristics of the coil, this can cause total breakdown of complex compounds, such as in the degradation of organic molecules in the presence of an oxidant for the subsequent measurement of total N, C, or, with milder conditions, partial decomposition as in the breakdown of complex cyanides to HCN.

## Dialysis

Dialysis was the first technique other than simple mixing to be developed for SFA. As shown in **Figure 3**, a donor stream consisting of the sample, normally diluted with a buffer or other reagent, passes over the surface of a permeable membrane made of cellulose acetate or similar material. A segmented stream of recipient reagent flows along the other side of the membrane (**Figure 1**, module 4). Ions and molecules with relative molecular mass less than ~1000, depending on the membrane type, diffuse through the membrane, while larger species such as fat and proteins remain in the donor stream. In a dialyzer of sufficiently long path length, equilibrium is eventually reached between donor and recipient streams. In practice, much shorter path lengths are usual, and the recovery of the wanted species is typically between 1% and 20%. Recovery depends on the path length, ionic strength, flow rates of the donor and recipient streams, temperature, and membrane type.

Dialysis was an important factor in the success of SFA in clinical applications, as it eliminated interference from blood lipids and protein, which formerly had to be removed by time-consuming manual procedures. In industrial applications, dialysis is commonly used to separate interfering materials such as those found in wastewater, and as a simple means of diluting high-concentration samples.

A variant of dialysis uses a membrane made of polytetrafluoroethene (PTFE), silicone rubber, or other hydrophobic material. These membranes allow the passage of gas while remaining impervious to liquids and dissolved solids. They are used in the determination of CO<sub>2</sub>, NH<sub>3</sub>, HCN, and other gases, either directly in the sample or following a reaction

**Figure 3** Online distillation in an SFA system.

to liberate them from other compounds present in the sample. An example is the enzymatic determination of lysine in food extracts. In this method, lysine decarboxylase degrades the amino acid to  $\text{CO}_2$ .  $\text{CO}_2$  in the donor stream diffuses through a gas-permeable membrane mounted between the plates of a conventional dialyzer into the recipient stream containing weakly buffered phenolphthalein, causing a color change that is measured photometrically.

## Distillation

This lengthy manual procedure is automated with SFA by passing the sample stream through a coil in a high-temperature heating bath, typically at 150°C (Figure 3). A nonvolatile liquid such as sulfuric acid or glycerol is added to the sample before distillation to maintain a liquid coating on the inner surface of the coil as the water evaporates. The vapor passes into a separation column and from there to a condenser, while the involatile residue is pumped to waste. After condensation, the sample stream is pumped into the analytical manifold for subsequent reaction.

Distillation is used to separate impurities, especially in the analysis of phenol and fluoride. If sulfuric or phosphoric acid is used as the distillation reagent, the combination of high temperature and the high acid concentration inside the distillation coil after most of the water has evaporated can also be used to decompose compounds such as polyphenols and complex cyanides.

## Solvent Extraction

When two immiscible liquids pass through a continuous-flow system they form alternating segments analogous to the gas-liquid segments in conventional SFA. The intrasegment motion as the segments pass along the manifold results in counter-current extraction at each phase interface, and solutes generally reach equilibrium between the two phases within 2 min. Phase separation normally relies on differences in density between the phases. Air segmentation is not usually necessary, although it is frequently used as a way of preventing small segments of each liquid phase from coalescing into larger segments that would hinder the extraction process and be more difficult to separate when their volume approaches that of the phase separator. When no air is present separation can take place through a hydrophobic membrane.

One application of solvent extraction in SFA is the determination of anionic surfactants in water, where methylene blue ion pairs are extracted into chloroform. Another is the determination of histamine in blood serum; here, interference is removed by extraction into butanol and back-extraction into an aqueous phase prior to the measurement of histamine by the formation of a fluorescent compound with *o*-phthalaldehyde.

Other techniques have been developed for SFA to solve specific problems. In continuous filtration the sample stream is pumped onto the upper surface of a moving strip of filter paper and the clarified filtrate is withdrawn by suction from the underside. Another

unit, now obsolete, was developed for continuous Kjeldahl digestion; the sample and digestion mixture were pumped into a rotating glass helix placed above heating elements. In practice, few compounds were completely decomposed in the short reaction time that could be achieved.

## Detectors and Peak Measurement

The first detector to be used for SFA was a photometer, and photometric determinations still form the vast majority of current methods. Other detectors in common use are UV spectrophotometers, used primarily for pharmaceutical compounds and for bitterness in beer; flame photometers, for potassium and sodium determination; fluorimeters, used primarily for measuring low levels of determinants in the presence of interferences, such as the determination of histamine in blood, and vitamins in food extracts; and ion-selective electrode and pH detectors. In principle, almost any detector with flow-through capability can be used with SFA systems, and determinations based on densitometry, thermometry, and luminescence have been published, among others.

Peak height is used almost exclusively as the basis for measurement in SFA. Commonly, the sample aspiration time is chosen so that the response in the detector reaches a constant or nearly constant value, giving a peak with a flat top. The signal from this steady-state section of the peak is averaged to give the final result. If the system has an irregular response, the sampling time can be extended to prolong the steady state, allowing irregularities due to hydraulic effects of unwanted solid particles or air bubbles in the stream to be eliminated. This mode of peak reading gives more accurate results than peak height measurements from sharp peaks such as those produced by chromatography or flow injection systems, and does not require the signal to return to near the baseline as does area-based calculation.

Evaluation of the peaks from a long run can follow up to four stages. First, the baseline at the beginning and end of a series of peaks is measured and the calculated baseline position for each peak, assuming linear drift, is subtracted from the overall peak height to give a baseline-corrected value. Second, sample interaction or carryover may be calculated from a set of known peaks and the contribution to each peak from the previous one subtracted. Third, if standards of known concentration have been repeated throughout the run, they can be used to calculate any change in sensitivity and this can be corrected. Finally, the corrected peak values are used to define the standard curve and the sample results are calculated.

## System Design and Development

### Dispersion

The purpose of Skeggs' innovation in flow analysis – the introduction of air bubbles into the flowing stream – was to reduce dispersion, so as to minimize the time taken for a steady-state condition to be reached in the detector. It was only in the 1970s that the definitive description of dispersion in segmented streams was derived by Snyder and Adler. This showed a complex relationship between internal diameter, liquid flow rate, segmentation frequency, residence time in the flow system, viscosity of the liquid, and surface tension. The most important conclusions from this model are, first, that for any given tubing diameter there are optimum values for flow rate and segmentation frequency to achieve minimum dispersion, and, second, that dispersion can be decreased without limit by reducing tubing diameter.

Other sources of dispersion are the transmission tubing carrying the sample from the autosampler to the pump, and the flow cell, where a debubbler removes the air segmentation before the liquid stream passes through the light path. The advent of electronic or software means for eliminating interference from air bubbles passing through the flow cell, sometimes known as bubble-gating, eliminated the need for flow cell debubblers and was a major contributor to reducing total system dispersion. Sample line dispersion can be reduced by introducing several air bubbles between samples and the intersample wash, using a so-called pecking-probe sampler. In practice, this is only useful for viscous samples such as blood serum.

The advances in system design roughly halved dispersion and doubled analysis rate with each new generation; a heated reaction stage would run at 30 samples per hour on a first-generation system, 60 per hour on a second-generation system, and 120 per hour on third-generation systems using 1 mm hydraulics (1 mm diameter tubing).

### Hardware

The first commercially available SFA system, the AutoAnalyzer, was produced in 1957 and remained in production for ~10 years. During this time all parts of the system underwent rapid design changes until, at the end of its life, it was very similar in principle to modern systems. The first systems, for example, aspirated air between samples, rather than using an intersample wash solution. This resulted in accumulations of analyte in the sample tubing and correspondingly high interaction between subsequent samples. The innovation of a water wash between

samples automatically introduced by the sampler first appeared in 1961.

The second generation of SFA hardware was introduced first in 1967 and subsequently in modular form in 1970; this system was being produced until 1997. These systems incorporated refinements whose effect was to increase the rate and precision of analysis. The sampler had a faster action so as to minimize the time the sample probe aspirated air between sample and wash, thus reducing the volume of the intersample air bubble and its consequential effect on the elasticity of the analytical stream; the pump incorporated an 'air bar' to introduce air bubbles of constant volume synchronized with the pulsation of the rollers, thus ensuring that every liquid segment contained the same volume of reagents and sample: the manifold tubing was reduced in internal diameter from 2.4 to 2.0 mm and was constructed almost entirely of high-tolerance glass, thus ensuring stable flow and reducing flow rates and reagent consumption. The debubbler needed to remove the air bubbles before the flow cell was integrated into the flow cell itself, greatly reducing the unsegmented volume with a corresponding reduction in dispersion and increase in sample rate. Flow rates were  $\sim 2 \text{ ml min}^{-1}$ , about half those of the earliest SFA systems.

Multichannel systems were produced for clinical analysis. Before microprocessors were available for calculating results, these systems used a combination of hydraulic phasing and mechanical timers to switch the steady-state part of each peak sequentially for each channel onto calibrated chart paper.

In 1975, a fully computer-controlled system was introduced that could run 20 channels in parallel. The hydraulics were designed for the first time with a proper understanding of the factors determining dispersion, and incorporated 1 mm glassware, liquid flow rates of  $\sim 0.5 \text{ ml min}^{-1}$ , and a segmentation frequency of 90 bubbles per minute, compared to  $30 \text{ min}^{-1}$  on the earlier systems. The bubbles passed directly through the flow cell, without debubbling, and their interference was eliminated electronically. These improvements resulted in a doubling of sampling rate and halving of flow rates, giving one-fourth the reagent consumption per sample.

This system was dedicated to clinical analysis, and marked a split in development between clinical and industrial systems. The wider variety of sample types and analytical requirements in the industrial market catalyzed the development of techniques such as distillation and UV digestion. Subsequently, 1 mm hydraulics were introduced to industrial systems and computer control enabled automatic photometer control and dilution of over-range samples.

## Further Developments

With the advent of systems using 1 mm hydraulics, with liquid and air deliveries close to the theoretical optimum, further reduction in dispersion could only be achieved by using smaller diameter tubing. This would place such high demands on pump design and so increase the risk of blockage that no system with smaller hydraulics has been produced commercially, and further reduction is unlikely. A system with theoretically zero carryover was introduced in 1987, designed for clinical laboratories. It used hydrophobic tubing that is coated internally with an inert fluorocarbon liquid. Aqueous segments were completely contained within the fluorocarbon, analogous to the air bubbles in a normal segmented system, and thus the thin film of liquid allowing adjacent segments to interact – the source of carryover – is absent.

A system introduced in 1992 can use an injection valve to introduce the sample into the flowing stream, which may be unsegmented, for FIA applications, or air-segmented to accommodate long reactions.

Other system improvements have centered on easier operation and higher automation. Computers, originally used only for calculating results, have taken over system control to automate functions such as photometer baseline and gain setting, and the control of random-access samplers. These samplers allow samples that fall off-scale to be diluted and reanalyzed in an extension to the original analysis run, so avoiding the need for manual dilution and re-run. An accessory to one system allows the reagents for several different tests on a multimethod manifold to be switched automatically between runs, allowing a single channel to be used for multiple analyses.

## Applications

The main fields of applications for SFA systems are, in order of current importance, water, soil and plant extracts, tobacco, food and beverages, chemical production, and clinical analysis. The reasons for the decline of the formerly dominant clinical market have been described; pharmaceutical applications, also previously important, have declined because standard methods developed for new products are generally based on separative techniques, especially liquid chromatography (LC). Table 1 shows the most common applications of SFA.

### Water Analysis

SFA is the dominant technique for the routine automated determination of ions in drinking, surface,

ground, waste, and sea water. Although FIA has made inroads into this area, its inability to accommodate reactions taking longer than  $\sim 1$  min while maintaining high analysis rates is sometimes disadvantageous, and complex determinations involving UV digestion or distillation, such as the measurement of total cyanide in wastewater, are more difficult to automate by FIA due to the high amount of dispersion generated. More recently, discrete analyzers, which use robotics to dispense small volumes of samples and reagents into a separate reaction vessel for each test, have started to enter the water analysis market. However, they are unable to perform the complex tests described above. Since 1995 several SFA methods for water and waste water have received ISO standard certification, including

nitrate, phosphate, total phosphorus, and ammonia. The ISO standard methods are documented for both SFA and FIA.

A simplified flow diagram for the SFA method for total cyanide is shown in **Figure 4**. The sample is acidified and passes through an online UV digester, where metallic cyanide complexes are decomposed into  $\text{CN}^-$  ions. The power and wavelength characteristics of the lamp are such that further breakdown into C and N radicals does not occur. Following digestion, the sample is acidified and distilled to separate the cyanide as HCN. The distillate is condensed and the cyanide ions react with pyridine and barbituric acid, producing a colored compound measured at 570 nm. Variations on the distillation stage of this analysis have been developed; in one method a stream of air is passed through the distillation system, resulting in a shorter residence time and lower dispersion; in another, the distillation stage is replaced by a gas dialyzer.

**Table 1** Applications of segmented flow analysis

<i>Water analysis</i>	<i>Food and drink</i>
Acidity	Alcohol
Alkalinity	Amylase

Potassium	

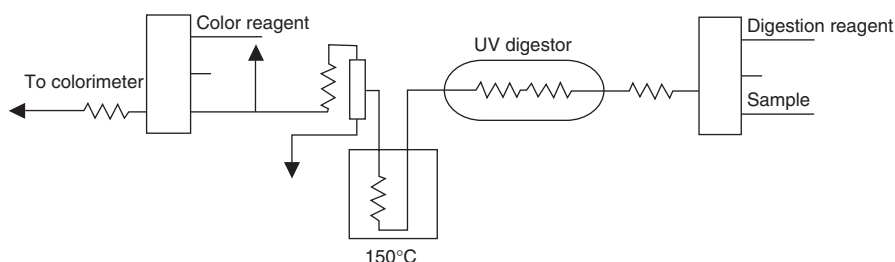

Well over 1000 SFA methods have been documented; this is a summary of the most common nonclinical applications in current use.

### Continuous Monitoring

SFA lends itself to continuous operation, and most methods can be run with a continuous flow of sample, rather than connected to sample changer. More than 100 papers specifically concerning online applications of SFA have been published. Modified laboratory systems have been less successful than those specially designed for continuous use, largely due to limited pump tube life and difficulties associated with calibration and sample introduction. In many online applications a response time of 10–15 min is adequate, and so the benefits of gas segmentation in limiting dispersion are questionable. As a result, many of the most successful commercial systems operate without air bubbles. The division between some of these systems and FIA systems is not sharply defined.

### Interface with Other Systems

SFA systems have been used with LC both for sample preparation before chromatography and for postcolumn derivatization. Sample purification by dialysis, filtration, or solvent extraction can be conveniently

**Figure 4** Simplified flow diagram for total cyanide determination with UV digestion and distillation.

performed with segmented flow. The low band broadening in segmented streams is advantageous both in precolumn sample preparation to allow lengthy cleanup procedures and postcolumn to maintain peak separation. In these hybrid systems, the output from the SFA manifold is pumped through the LC sample loop, which is actuated by a timer when sample concentration has reached its maximum.

Dialysis and solvent extraction are the most commonly used precolumn techniques. In an SFA unit specially developed for LC sample preparation to ensure solvent compatibility with the mobile phase, the evaporation to dryness module, sample dissolved in a volatile organic solvent is pumped onto a moving PTFE wire; the solvent is evaporated in a stream of hot gas and the residue redissolved in a second solvent compatible with the chromatography system.

Applications of SFA/LC include the determination of drugs in blood serum, pharmaceutical product analysis, and the determination of vitamin A in milk.

# SELENIUM

**P C Uden**, University of Massachusetts at Amherst, MA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Selenium (Se) is essential for animals and humans, causing disease by deficiency, but being toxic on ingestion at an order of magnitude above essentiality. It is present in the environment in inorganic and organic chemical species and analytical speciation is vital as bioavailability and toxicity depend on the binding form.

## Selenium in the Environment

Selenium has six natural stable isotopes:  $^{74}\text{Se}$  (0.9%),  $^{76}\text{Se}$  (9.4%),  $^{77}\text{Se}$  (7.6%),  $^{78}\text{Se}$  (23.8%),  $^{80}\text{Se}$  (49.6%), and  $^{82}\text{Se}$  (8.7%). It usually occurs in the sulfide ores of the heavy metals but rarely as the free element. Volcanic soils are enriched in selenium as are some coal deposits. Selenium compounds are volatilized during the fuel combustion and during copper and other metal smelting and refining. There are numerous overviews of selenium with extensive information on geochemistry and occurrence, seleniferous

environments, solubility, speciation and transformation of selenium in soils, bioaccumulation, etc.

Selenate ( $\text{SeO}_4^{2-}$ ) is thermodynamically stable in alkaline and oxidized environments. Selenates are soluble in water and less strongly adsorbed than selenite ( $\text{SeO}_3^{2-}$ ), easily leached from soils, transported to ground waters, and readily taken up by plants. Selenite occurs in mildly oxidizing neutral pH environments, is less soluble than selenate, is strongly adsorbed by particles, and may be reduced to elemental  $\text{Se}^0$ . Selenides ( $\text{Se}^{2-}$ ) exist in reducing acidic environments but are very insoluble, resist oxidation, and are not taken up by plant and animals. Selenium pollution of waters, sediments, and soils results from industrial activities such as oil refining, aqueous discharges from the storage of coal, coal ash landfill, etc.

The toxicity of selenium depends on its biologically active form. In alkaline soils and oxidizing conditions, it may be oxidized enough to maintain its biological availability and be taken up by plants, but in acidic or neutral soils, it tends to remain relatively insoluble and biologically unavailable. It accumulates in living tissues and its level in human blood is  $\sim 200 \text{ ng ml}^{-1}$ . Selenium has been found in marine fishmeal at levels of  $\sim 2 \mu\text{g per g}$ ,  $\sim 50\,000$  times above that in seawater.

Selenium dioxide is an industrial exposure hazard since it forms selenite, an irritant, with water or

# SAPONINS

**K Hostettmann and A Marston**, Université de Lausanne, Lausanne-Dorigny, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

This article is reproduced from the previous edition, pp. 4540–4544, © 1995, Elsevier Ltd., with an updated Further Reading list supplied by the Editor.

## Introduction

Saponins are  $C_{27}$  or  $C_{30}$  natural product glycosides. They are distributed widely in plants, sometimes in very large amounts. Saponins have surface-active properties and often foam strongly when shaken with water. Saponins consist of one or more linear or

branched sugar chains linked to an aglycone. There are three main classes of these glycosides:

- (1) triterpene glycosides;
- (2) steroid glycosides; and
- (3) steroid alkaloid glycosides.

Examples of the basic skeleton (aglycone) of these saponins are to be found in **Figure 1**. Hydroxylation at the carbon C-3 is almost always found, but functionalization at other positions is common. Monodesmosidic saponins have a single sugar chain attached normally at position C-3. Bidesmosidic saponins have two sugar chains, usually with one attached through an ether linkage at C-3 and the other at C-28 (triterpene saponins) or at C-26 (steroid saponins) or at C-26

**Figure 1** Aglycone skeletons of saponins.

(steroid saponins). Both pentacyclic (with  $\beta$ -amyrin,  $\alpha$ -amyrin, or lupeol skeletons) and tetracyclic (dammarane and lanostane) triterpene saponins are encountered frequently (Figure 1).

Saponins are distributed widely in the plant kingdom, with many examples to be found in plant foodstuffs such as sugar beet, potatoes, tomatoes, soya beans, peas, beans, and yams. The angiosperms are very rich sources of triterpene glycosides, and while these saponins have also been found in pteridophytes, they are virtually absent in the gymnosperms. Triterpene saponins are most often found in the dicotyledons (dammarane glycosides are frequent in the families Araliaceae, Cucurbitaceae, and Rhamnaceae), and steroid saponins are characteristic of the monocotyledons (especially the families Liliaceae and Dioscoreaceae). Steroid alkaloid glycosides are distributed widely in the family Solanaceae.

Certain marine organisms (sea cucumbers, sea urchins, and starfish) contain varying amounts of saponins, mainly for defense purposes.

## Sampling and Sample Pretreatment

The glycosidic nature of saponins means that they are polar compounds and often water-soluble. In extracts from plants, they are accompanied by sugars and phenolic material. Extraction is best achieved with methanol, ethanol, or aqueous mixtures of these alcohols. A defatting step needs to be included, either before or just after extraction with alcohol. In the past, precipitation with lead acetate, barium hydroxide, and tannic acid and salting-out with ammonium sulfate or magnesium sulfate was carried out. Precipitation with cholesterol is still sometimes performed. However, contemporary methods involve precipitation with diethyl ether, or dialysis to remove small water-soluble molecules. A final partition step between water and *n*-butanol is useful in concentrating saponins in the organic layer. Once obtained, these enriched preparations may contain complex mixtures of closely related compounds, differing in the nature of the aglycone or sugar moieties (nature, number, and position of attachment of the saccharides).

More recent sample preparation steps, especially for liquid chromatographic applications, have involved prepurification of extracts on Sep-Pak C<sub>18</sub> (or similar) cartridges. Glycoalkaloids may be purified preliminarily on Sep-Pak C<sub>18</sub> or NH<sub>2</sub> cartridges.

## Nonchromatographic Methods for Determination of Saponins

Several nonchromatographic methods have been employed for the identification and determination of

saponins – namely hemolysis, piscicidal activity, gravimetry, and ultraviolet (UV)–visible spectrophotometry. These are being replaced rapidly by chromatographic techniques, but hemolysis and UV–visible spectrophotometry are still of some importance.

### Hemolysis

One characteristic of many (but not all) saponins is their capacity to rupture erythrocytes (red blood corpuscles). By measuring the change in absorbance of the supernatant of an erythrocyte suspension after hemolysis, the saponin content can be calculated. Various amounts of the saponin-containing product or extract are mixed with a suspension of washed erythrocytes in isotonic buffer at pH 7.4. After 24 h, the mixture is centrifuged and hemolysis is indicated by the presence of hemoglobin (red) in the supernatant. In the European Pharmacopoeia, the quantity in milliliters of ox blood (diluted 1:50) that is totally hydrolysed by 1 g of test substance is measured. As a standard, the saponin mixture from the roots of *Gypsophila paniculata* (Caryophyllaceae) has by definition an activity of 30 000 units.

### UV–Visible Spectrophotometry

Unsaturated and hydroxylated triterpenes and steroids give colored products with aromatic aldehydes in strong mineral acids, with acetic anhydride in sulfuric acid, and with inorganic salts (cerium(IV) sulfate and antimony(III) chloride, for example) in an acidic solution. These reactions have been used as the basis for determination of saponins. The analysis of *Ginseng radix* (*Panax ginseng*, Araliaceae) in Pharmacopoeia Helvetica VII, for example, relies on reaction with glacial acetic acid/sulfuric acid and spectrophotometric determination at 520 nm of the red product. The  $\beta$ -aescine component of horse chestnut (*Aesculus hippocastanum*, Hippocastanaceae) saponin can be determined spectrophotometrically after treatment with a mixture of iron(III) chloride, acetic acid, and sulfuric acid.

## Chromatographic Methods

Spectrophotometric methods are sensitive but not really suitable for estimating saponins in crude plant extracts since the reactions are not specific and colored products may form with accompanying compounds such as phytosterols and flavonoids. Similarly, hemolytic methods also suffer from a lack of specificity. Consequently, alternative ways of analyzing for saponins using different chromatographic techniques have been developed.

### Thin-Layer Chromatography

Thin-layer chromatography (TLC) is of fundamental importance for both the identification and determination of saponins. Both pure products and crude extracts can be handled, the equipment is simple and inexpensive, and results can be obtained rapidly. A number of visualization reagents are available for spraying the TLC plates and give color reactions for the different classes of saponins (Table 1). For quantitative spectrophotometry, the required constituents are separated on the TLC plate, scraped off, and then extracted with a suitable solvent, such as ethanol. After treatment with a reagent, the colored solution is measured at a specified wavelength.

### Liquid Chromatography

Liquid chromatography (LC) is technically much more complicated than TLC. Its speed, sensitivity, and adaptability to nonvolatile polar compounds is ideal for the analysis of saponins and sapogenins. The vast majority of separations have been performed on octadecylsilyl columns, with acetonitrile–water mixtures as the eluent, although occasionally methanol–water mixtures and low concentrations of acid have been used. Acetonitrile is preferred to methanol at short wavelengths because of its smaller UV absorption. As long as gradient changes are small, UV detection (between 203 and 215 nm) is possible. An example of the separation of bidesmosidic saponins from berries of *Phytolacca dodecandra* (Phytolaccaceae) is shown in Figure 2. This used a shallow acetonitrile–water gradient and an RP-8 column. The more polar glycosides of bayogenin (1 and 2 in Figure 2) and hederagenin (3) were separated before the oleanolic acid derivatives (4–6). However, if the polarity difference of the saponin mixture is not too great, isocratic elution is sufficient for the separation.

The lack of a suitable strong chromophore is the reason for certain difficulties when chromatographing saponins. This problem can be overcome by

changing the detection method and employing refractive index and mass detectors, although these techniques have their own inherent complications. An alternative, assuming that the saponin has a suitable functional group, is to derivatize the sample, for example, the free carboxyl group often found in triterpene glycosides can be functionalized with 4-bromophenacyl bromide in the presence of potassium hydrogencarbonate and a crown ether (Figure 3). 4-Bromophenacyl derivatives absorb strongly at 254 nm, and UV detection can be performed at this wavelength without interference from the solvent. By this means, quantification of molluscicidal monodesmosidic saponins in aqueous extracts of *P. dodecandra* berries was possible (Figure 4). Analysis was performed on an RP-18 column with an acetonitrile–water gradient. Because derivatization of the extract allowed the introduction of a chromophore into the triterpene part of the molecule, the saponins were detected at 254 nm. Alfalfa (*Medicago sativa*, Fabaceae) root saponins have also been determined using this method. Alternative methods for analysis of poorly UV active saponins are used to prepare benzoate esters, fluorescent coumarin derivatives, or dienes.

To avoid peak-broadening, some method of suppressing ion formation (of free carboxyl groups on the aglycone or saccharide moieties, for example) is required. This can be achieved by addition of a low UV-absorbing acid such as phosphoric acid or trifluoroacetic acid to the eluent. Another possibility is to use ion pair LC, with a counterion added to the mobile phase. The capacity factor of the ionic compounds is increased by forming ion complexes with the pairing reagent.

**Figure 2** LC of a methanolic extract of *P. dodecandra* berries. Column, RP-8; eluent, acetonitrile–water gradient from 28% to 38% acetonitrile in 20 min; flow rate, 1.5 ml min<sup>-1</sup>; detection, UV, 206 nm. 1 and 2, polar glycosides of bayogenin; 3, polar glycoside of hederagenin; 4–6, oleanolic acid derivatives.

Water

**Figure 3** Derivatization of saponins with a UV-active chromophore.

**Figure 4** LC analysis of a derivatized aqueous extract from *P. dodecandra* berries. Column, NovaPak C<sub>18</sub> 4  $\mu\text{m}$  (150 mm  $\times$  3.9 mm); eluent gradient from 40% to 70% acetonitrile over 45 min; flow rate, 1 ml min<sup>-1</sup>; detection, 254 nm. Peaks 7–9 correspond to structures 7–9 at the top of this figure.

If peak resolution on reversed-phase LC columns is insufficient, other approaches are to use hydroxyapatite or chemically modified porous glass columns or to carry out the LC of borate complexes.

Glycoalkaloids can be separated and quantified on RP-18 or amino columns. The solvent combination acetonitrile–water–potassium dihydrogenphosphate is indicated for the latter columns.

### Gas Chromatography

Rather than measuring saponins themselves, gas chromatography (GC) has been used to quantify aglycone moieties as their trimethylsilyl ethers after hydrolysis of parent saponins. This indirect method has been applied to the analysis of dammarane

glycosides from ginseng, analysis of soya bean saponins, and determination of 18 $\beta$ -glycyrrhetic acid after hydrolysis of *Glycyrrhiza* glycosides. Analysis of intact trimethylsilylated triterpene glycosides containing four sugar units or less from ginseng is also possible.

### Selected Applications

For determinations of saponins, LC is now the technique of choice, and better results are thereby obtained compared with UV–visible spectrophotometry, GC, and TLC. The amounts of the individual saponins in a mixture or extract can be determined, and adulterations are easier to discern.

For example, LC is now used routinely for quality control of commercial ginseng (*P. ginseng*) preparations and of the plant material itself. Dried vegetable material is extracted with methanol–water (80:20; v/v) at 60°C. After evaporation of the solvent, the extract is dissolved in water and introduced onto a Sep-Pak C<sub>18</sub> cartridge. Following washing with water and methanol–water (30:70; v/v), the saponins are eluted with methanol and then determined on an octadecylsilyl column (usually 5 µm). A typical elution profile with an acetonitrile–water solvent acidified with 1% phosphoric acid (15:85; v/v; A) and acetonitrile–water (80:20; v/v; B) is the following: 10 min with 10% B in A (isocratic), 15 min with a 10–20% linear gradient of B in A, 15 min with a 20–35% linear gradient of B in A, and 10 min with 35% B in A (isocratic). Elution is at 1 ml min<sup>-1</sup> and detection at 205 nm. By this means the glycosides of (20S)-protopanaxatriol, ginsenosides Rg<sub>1</sub>, Re, Rf, and Rg<sub>2</sub>, are eluted before the glycosides of (20S)-protopanaxadiol, ginsenosides Rb<sub>1</sub>, Re, Rb<sub>2</sub>, and Rd, in that order.

β-Aescine, the active constituent of *Aesculus hippocastanum* (Hippocastanaceae), has important antiinflammatory, antiedematous, and capillaro-protective properties. It is used in therapy of peripheral vascular disorders. β-Aescine is a mixture of saponins, but for standardization purposes, the two main glycosides of protoaescigenin can be determined by

LC. Samples of β-aescine are dissolved in water and analyzed on 5 µm RP-18 columns with the solvent system acetonitrile–water–20% phosphoric acid (33.5:66.5:0.1; v/vv), pH 3.2, at a flow rate of 1 ml min<sup>-1</sup> and UV monitoring at 205 nm.

Other determinations using LC employ similar procedures: these include analyses of licorice extracts, saikosaponins from *Bupleuri radix*, ivy (*Hedera helix*, Araliaceae) saponins, and saponins from *Primula veris* and *P. elatior* (Primulaceae).

performed with segmented flow. The low band broadening in segmented streams is advantageous both in precolumn sample preparation to allow lengthy cleanup procedures and postcolumn to maintain peak separation. In these hybrid systems, the output from the SFA manifold is pumped through the LC sample loop, which is actuated by a timer when sample concentration has reached its maximum.

Dialysis and solvent extraction are the most commonly used precolumn techniques. In an SFA unit specially developed for LC sample preparation to ensure solvent compatibility with the mobile phase, the evaporation to dryness module, sample dissolved in a volatile organic solvent is pumped onto a moving PTFE wire; the solvent is evaporated in a stream of hot gas and the residue redissolved in a second solvent compatible with the chromatography system.

Applications of SFA/LC include the determination of drugs in blood serum, pharmaceutical product analysis, and the determination of vitamin A in milk.

## Introduction

Selenium (Se) is essential for animals and humans, causing disease by deficiency, but being toxic on ingestion at an order of magnitude above essentiality. It is present in the environment in inorganic and organic chemical species and analytical speciation is vital as bioavailability and toxicity depend on the binding form.

## Selenium in the Environment

Selenium has six natural stable isotopes:  $^{74}\text{Se}$  (0.9%),  $^{76}\text{Se}$  (9.4%),  $^{77}\text{Se}$  (7.6%),  $^{78}\text{Se}$  (23.8%),  $^{80}\text{Se}$  (49.6%), and  $^{82}\text{Se}$  (8.7%). It usually occurs in the sulfide ores of the heavy metals but rarely as the free element. Volcanic soils are enriched in selenium as are some coal deposits. Selenium compounds are volatilized during the fuel combustion and during copper and other metal smelting and refining. There are numerous overviews of selenium with extensive information on geochemistry and occurrence, seleniferous

environments, solubility, speciation and transformation of selenium in soils, bioaccumulation, etc.

Selenate ( $\text{SeO}_4^{2-}$ ) is thermodynamically stable in alkaline and oxidized environments. Selenates are soluble in water and less strongly adsorbed than selenite ( $\text{SeO}_3^{2-}$ ), easily leached from soils, transported to ground waters, and readily taken up by plants. Selenite occurs in mildly oxidizing neutral pH environments, is less soluble than selenate, is strongly adsorbed by particles, and may be reduced to elemental  $\text{Se}^0$ . Selenides ( $\text{Se}^{2-}$ ) exist in reducing acidic environments but are very insoluble, resist oxidation, and are not taken up by plant and animals. Selenium pollution of waters, sediments, and soils results from industrial activities such as oil refining, aqueous discharges from the storage of coal, coal ash landfill, etc.

The toxicity of selenium depends on its biologically active form. In alkaline soils and oxidizing conditions, it may be oxidized enough to maintain its biological availability and be taken up by plants, but in acidic or neutral soils, it tends to remain relatively insoluble and biologically unavailable. It accumulates in living tissues and its level in human blood is  $\sim 200 \text{ ng ml}^{-1}$ . Selenium has been found in marine fishmeal at levels of  $\sim 2 \mu\text{g per g}$ ,  $\sim 50\,000$  times above that in seawater.

Selenium dioxide is an industrial exposure hazard since it forms selenite, an irritant, with water or

sweat. Other selenium compounds released during coal or petroleum combustion may be significant sources of exposure. Biogeochemical cycling involves geological erosion and anthropogenic influences to introduce selenium to sea water, mainly as selenite and selenate, at levels below  $1 \text{ ng ml}^{-1}$ . It is incorporated into organoselenium compounds in phytoplankton, zooplankton, lower and higher vertebrates, such pathways being considered to involve biomethylation. Natural selenium levels in soils vary widely from below  $100 \text{ ng per g}$  to  $10 \text{ } \mu\text{g per g}$  or above. Selenium volatilization contributes an estimated  $6 \times 10^6 \text{ kg}$  selenium per year to the atmosphere, dimethyl selenide and dimethyl diselenide being proposed as primary selenium carrier species. The concentrations in most plants and agricultural crops are below  $1 \text{ mg per kg}$  but some grown in selenium-rich soils may accumulate selenium to concentrations of several thousands of  $\text{mg per kg}$  dry mass. Hyperaccumulating plants such as *Brassica juncea* can also be used to remove selenium from contaminated soils by phytoremediation. Table 1 lists selenium species identified in the environment, inorganic forms and methylated species, selenoamino acids, selenoenzymes, and selenium nucleic acids. Traces of selenium ranging from  $0.001$  to  $10 \text{ ng l}^{-1}$  are found in drinking water. Concentrations of dimethyl selenide and dimethyl diselenide in air samples have been reported at  $\text{ng m}^{-3}$  levels.

Selenium's ecotoxicity is complex since selenium exists in many chemical forms, each of which has a different bioavailability and ecotoxic potential. Cytotoxic selenium species, such as selenocysteine, catalyze formation of free radicals and may be

harmful at very low concentration, but other species such as selenomethionine may present an ecotoxic threat without being directly cytotoxic. Organisms at higher trophic levels, such as birds, obtain most of their selenium from eating lower trophic level organisms, so the chemical forms of selenium to which they are primarily exposed may vary. The key to a mechanistic biochemical understanding of selenium ecotoxicity lies in a more complete knowledge of the processes of speciation, biotransformation, and accumulation in the food chain.

The many selenium species present in environmental and biological materials present a great analytical challenge. Biologically selenium is not bound by coordination but forms covalent C–Se bonds. Enzyme products arise from reactions such as reduction, methylation, and selenoamino acid synthesis. Selenium is incorporated into gene products, according to the UGA codon that encodes for the selenocysteinyl residue. To elucidate the complexities of selenium chemistry, the determination of 'total element', although essential to determine element mass balance, provides insufficient information and must be accompanied by speciation of selenium compounds, as related to biochemical cycles such as shown in Figure 1.

## Speciation of Nutritional Selenium

Differences in the selenium content of foodstuffs are due in part to geographical differences in the amounts of the element that are transferred from soil to the food chain. Selenium-deficiency diseases related to selenium-poor soil are recognized in parts of China and elsewhere, but soils rich in selenium (above  $5 \text{ ppm}$ ) are found in parts of the United States. The selenium in most plant-derived foods, present substantially as selenomethionine (SeMet) and selenocysteine (SeCys) derivatives, has reasonably good bioavailability. However, in animal-derived foods selenium has a wide range of bioavailability as assessed by its ability to increase liver concentrations and glutathione peroxidase activity.

Selenium was recognized as nutritionally significant in the late 1950s and in the 1970s: a discrete metabolic function was found as an essential component of the enzyme glutathione peroxidase (GPX) that contributes to antioxidant protection of cells by reducing hydroperoxides. Several selenium enzymes are now recognized, GPX isoforms, iodothyronine 5'-deiodinases (DIs), thioredoxin reductases (TRs), selenophosphate synthetase, and plasma selenoprotein P (SeP), all containing selenocysteine (SeCys). The nutritional essentiality of selenium may be due to the formation of the active selenol group ( $-\text{SeH}$ ) of

**Table 1** Some selenium compounds in environmental and biological systems

### Inorganic species

$\text{Se}^0$  (element), selenide –  $\text{Se}^{2-}$ , selenate –  $\text{SeO}_4^{2-}$ , selenite –  $\text{SeO}_3^{2-}$

### Simple organic and methylated species

Methylselenol ( $\text{MeSeH}$ ), dimethylselenide ( $\text{Me}_2\text{Se}$ ), dimethyldiselenide ( $\text{Me}_2\text{Se}_2$ )

Trimethylselenonium cation ( $\text{Me}_3\text{Se}^+$ ), dimethylselenone ( $\text{Me}_2\text{SeO}_2$ )

Dimethylselenoxide ( $\text{Me}_2\text{SeO}$ ), methylseleninic acid anion ( $\text{MeSe(O)O}^-$ )

Dimethylselenosulfide ( $\text{MeSSeMe}$ ), selenourea ( $\text{Se}=\text{C}(\text{NH}_2)_2$ )

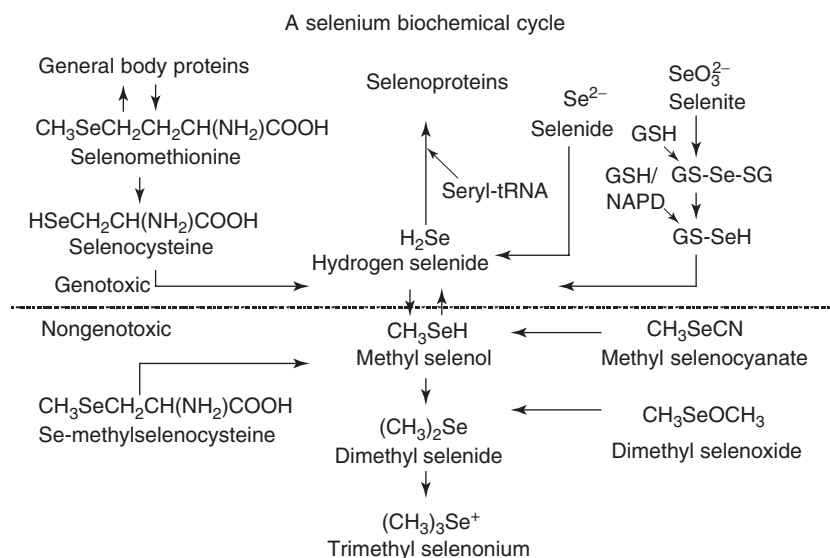

### Amino acids and low molecular mass species

Selenomethionine, selenocysteine, selenocystine, Se-methylselenocysteine, selenocysteic acid

Se-methylselenomethionine, selenomethionine selenoxide, selenocholine, selenobetaine

### Other compounds

Selenoproteins, selenoenzymes, Se-metal metallothionines

**Figure 1** Biochemical selenium pathways. (Reproduced from Uden C (2002) Modern trends in the speciation of selenium by hyphenated techniques. *Analytical and Bioanalytical Chemistry* 373: 423 (Figure 1); © Springer-Verlag.)

such SeCys proteins, antioxidant protection by the GPXs, energy metabolism affected by the DIs, and redox regulation of transcriptional factors and gene expression by the TRs.

Desirable selenium dietary levels span a relatively narrow range: food containing less than 0.1 mg per kg of food is deficient, but levels above 1 mg per kg lead to toxicity. Interest in selenium has focused on its role in the maintenance of low risk to cancer, relevant speciation studies being essential.

The *allium* plant family exhibits selenium chemistry and high-selenium garlic has found promise in mammary cancer prevention. At present, no selenium-enriched food or nutritional supplements have been fully characterized with respect to selenium compounds.

A common selenium supplement is 'selenized yeast', which has been evaluated in human nutritional clinical trials. The pattern of selenium compounds in different selenium-enriched products varies substantially. Only those made with active yeasts contain selenomethionine,  $\gamma$ -glutamyl Se-methylselenocysteine, and Se-adenosylselenohomocysteine, and perhaps other compounds with methyl-Se bonds such as Se-methylselenocysteine and methylselenides  $[\text{CH}_3]\text{SeR}$ , which may be the most directly anti-carcinogenic of the known selenium metabolites. Different selenized yeasts have been found to contain organically bound selenium in a range from 0% to 97% of total selenium with some showing only a few selenium species and others containing more than 20 different selenium compounds. **Figure 2** shows selenium-specific high-performance liquid

chromatography-inductively coupled plasma-mass spectrometry (HPLC-ICP-MS) chromatograms of enzymatic hydrolysis products of 1250 ppm selenium yeast using 0.1% HFBA ion pairing agent (right scale expanded).

## Selenium in Biology and Medicine

The essential metabolic need for selenium has as its basis formation of the active selenol group ( $-\text{SeH}$ ) center of glutathione peroxidase, thioredoxin reductase, and of other selenoenzymes. Cancer chemoprevention is associated with inorganic selenium salts, selenoamino acids, and other organoselenium compounds. Monomethylated forms of selenium such as methylselenol ( $\text{CH}_3\text{SeH}$ ) are thought to be important chemopreventive selenium metabolites. Many epidemiological studies have pointed to an inverse association of selenium status and risk to at least some cancers. Supplemental selenium has been found to promote cellular phenomena thought to be anti-carcinogenic, to support cellular redox regulation via GPXs and TRs, to enhance immune functions, to increase carcinogen metabolism, to promote apoptotic responses, and to inhibit angiogenesis (blood-vessel formation) in mammary cancer. In a multicenter, double-blind, randomized, placebo-controlled study a total of 1312 older Americans with histories of basal or squamous cell carcinomas of the skin were randomized to dietary supplement of selenium-enriched yeast (200  $\mu\text{g}$  Se per day) or placebo. After over 6 years of follow-up subjects taking supplemental selenium had lower incidences of total cancer, specifically cancers of the

**Figure 2** Selenium-specific HPLC–ICP-MS chromatograms of enzymatic hydrolysis products of 1250 ppm selenium-enriched yeast using 0.1% HFBA ion pairing agent (right scale expanded).

lung colon-rectum and prostate, and overall cancer mortality. Evidence suggests that anti-tumorigenic activities can be supported by metabolites of forms of the element that naturally occur in foods: the Se-amino acids, SeMet and SeCys, and methylated Se-compounds such as Se-methyl-SeCys. With varying efficiencies, these species can be converted to a number of selenium metabolites, including methyl-selenol ( $\text{CH}_3\text{SeH}$ ), which appears to be a key anti-tumorigenic metabolite. These findings make the consideration of ‘Se status’ important in the maintenance of overall health.

## Analytical Strategies

For practical speciation, an analytical method must be specific to a particular selenium species or that species must be separated in time or space before arriving at a selenium-specific detector. Radioimmunological assays for selenoproteins offer very low detection limits but require the proteins to be isolated in amounts sufficient for antibody production. Selenium has been speciated into selenate, selenite, elemental Se, and organoselenium using fractionation techniques and X-ray absorption spectroscopy, but little has been done in speciating organic forms.

The application of hyphenated methods, involves coupling of an electromigration or chromatographic technique with a mass spectral, atomic spectrometric, or other selenium-specific measurement. This may be offline, e.g., SDS-PAGE with instrumental neutron activation analysis, or online, as in HPLC–ICP-MS. Selenium chemistry may mirror sulfur chemistry, but as selenium species are typically present at three orders of magnitude below sulfur analogs, considerable analytical challenges occur. Sometimes, however, there are major differences between sulfur and selenium chemistries, notably in redox behavior.

Ionic, zwitterionic, and neutral selenium species are present in natural systems. **Table 2** shows selenium compounds of biological and clinical interest and species in living organisms are listed in **Table 3**. Selenoproteins contain selenocysteinyl residues but proteins that contain selenomethionyl residues are not formally classified as selenoproteins.

Analytical techniques for the determination of selenium species, including selenoproteins, have been reviewed. Many methods have only been applied to the commercially available standards and not to address specific biochemical problems.

The complexity of analyte matrixes and the low level of selenium compounds even in enriched samples make speciation difficult, but the combination of separation processes with selenium-specific detection is a powerful approach. High sensitivity is vital, and MS with an atmospheric pressure ionization source, such as the ICP, has proved successful for HPLC detection. Selenium presents problems due to moderate ionization efficiency and isobaric interferences, although these can be partly overcome with high-resolution mass spectrometers or dynamic reaction cell (DRC) technology. Significant isotopic overlap from  $^{40}\text{Ar}_2^+$  on the most abundant isotope  $^{80}\text{Se}$  (49.6%) may necessitate measurement of the less abundant isotopes  $^{82}\text{Se}$  (8.6%) or  $^{77}\text{Se}$  (7.6%) of total selenium.

## HPLC Modes for Selenium Speciation

Size exclusion, reversed-phase, paired ion reverse-phase, and ion exchange (cation and anion) HPLC have been used for selenium speciation. Size exclusion, also used in combination with affinity chromatography, has been used for the determination of selenoproteins and studies of interactions of selenium with proteins in the body. Ion-exchange and reversed-phase HPLC are often used for separation

**Table 3** Selenium species in living organisms

<i>Selenium in proteins</i>	
Selenoproteins	Selenocysteiny residues
Se-containing proteins	Selenomethionyl residues
<i>Nonprotein selenium species</i>	
Inorganic selenium	Selenite ( $\text{SeO}_3^{2-}$ ), selenate ( $\text{SeO}_4^{2-}$ )
Methylated selenium	Monomethylselenol, dimethylselenide, trimethylselenonium ions
Selenoamino acids	Selenocystine, selenomethionine, Se-methylselenocysteine, selenogluthathione

of Se(IV), Se(VI), selenomethionine, and other selenoamino acids. A polymer-based reverse-phase column separated selenocystine, selenomethionine, and trimethylselenonium cation, with detection limits of  $\sim 1 \mu\text{g l}^{-1}$  for each species. Anion exchange was used for speciation of *in vitro* gastrointestinal extracts of cooked cod by ICP-MS but the degree of separation was strongly dependent on the pH of the mobile phase. A polymer-based strong anion-exchange column resolved selenite, selenate, selenomethionine, and selenocystine at pH 8.5 with 3% methanol in the mobile phase to enhance the ICP-MS signal.

If a 250 mg sample of selenium-enriched yeast with a selenium content of 1200 mg per kg is taken into 5 ml of solution, and target compounds are present at 10% of the total concentration, then prior to separation, the concentration of selenium in solution is  $6 \text{ mg l}^{-1}$ . If the separation procedure produces a dilution of 100, the concentration of material after separation is on the order of  $60 \mu\text{g l}^{-1}$ . The low concentrations of the target species present a

challenge and sample pretreatment must not change the chemical forms of the target species, or must change them in a known and controllable fashion.

Selenite was measured in human urine after selenomethionine supplementation, by anion-exchange chromatography with  $25 \text{ mmol l}^{-1}$  NaOH in 2% methanol mobile phase and ICP-MS detection. The concentration found ranged from  $0.4$  to  $7.1 \mu\text{g l}^{-1}$ , while the total selenium concentration was from  $12.4$  to  $97.6 \mu\text{g l}^{-1}$ . Assisted online species conversion hydride generation atomic absorption spectrometry (AAS) was used for quantitative selenium speciation analysis of selenate, selenite, selenomethionine, and selenocystine in CRM 402 reference material. Biological samples and selenium species were quantified in certified reference materials by anion exchange with interfaced direction injection nebulization (ICPAES) and graphite furnace AAS. An important advance in ICP-MS technique involved detection as  $^{80}\text{Se}$  by a DRC MS method. The most comprehensive ion exchange separation of selenium species yet reported separated cations on a cation-exchange column at pH 3 with a gradient of pyridinium formate, and anions on an anion-exchange column at pH 8.5 with a TRIS salicylate mobile phase. Selenomethionine-Se-oxide was observed at a high level in selenized yeast and dimethylselenonium propionate in an algal extract.

Many organoselenium compounds, especially selenoamino acids, are insufficiently hydrophobic to be retained and separated on  $\text{C}_8$  and  $\text{C}_{18}$  reversed-phase stationary phases with salt-free aqueous mobile phases, but retention and separation is increased by using ion-pairing reagent such as trifluoroacetic acid (TFA) or octane sulfonic acid. Perfluorinated carboxylic acids ion-pairing agents afford better resolution and are advantageous for characterizing samples

containing many different classes of organoselenium compounds. TFA is a good general-purpose system but compromises between resolution and retention time. However, heptafluorobutanoic acid (HFBA) provides considerable resolution enhancement and allows separation of many additional organoselenium species including the *cis-trans* isomers of Se-1-propenyl-dl-selenocysteine; eight inorganic and organoselenium species coeluting within an early eluted band with TFA were fully separated with HFBA. The method can also determine selenoxides and organoanions. Anionic species show some retention as protonated forms retained by reversed-phase partition. Semipreparative-scale reversed-phase columns were used for two-dimensional HPLC to isolate fractions of selenized yeast extracts for online and offline investigations by ICP-MS. Wild-type and genetically modified selenium-accumulating *Brassica juncea* were speciated with HPLC-ICP-MS and ES-MS detection. A mixed ion-pair technique in which butanesulfonate and tetramethylammonium hydroxide were used simultaneously enabled resolution of selenite, selenate, selenocystine, selenourea, selenomethionine, selenoethionine, selenocystamine, and trimethylselenonium.

#### **Speciation of Biomacromolecular Selenium Species by HPLC-ICP-MS**

Although separation of biomacromolecular selenium species by size exclusion chromatography (SEC) is mainly based on the molecular weights of the analytes, adsorption and ion exchange effects can play an important role. Resolution of small compounds of similar molecular mass may be achieved in addition to the possibility of the detection of selenoproteins. SEC-ICP-MS has enabled speciation of a number of metals bound to various macromolecular ligands but has had limited success for selenoproteins, the large dilution factor for selenium limiting sensitivity in attempts to speciate glutathione peroxidase. SEC-HPLC was the first procedure to measure selenoprotein-P in human plasma, but it lacks the resolution and sensitivity for separation of the major selenium proteins; a human serum sample yielded three signals, but none coeluted with the glutathione peroxidase activity. Speciation of human breast milk whey gave four selenium signals corresponding to apparent molecular weights of 15, 60, 1500, and >2000 kDa. A combination of affinity chromatography with SEC-ICP-MS separated three major selenium-containing proteins (albumin, glutathione peroxidase, and selenoprotein-P) in human plasma. Selenium incorporation into cyanobacterial metallothionein induced under heavy metal stress

was studied using SEC-ICP-MS, two pathways being indicated. Selenite and selenate metabolism in rats was investigated and exchange of endogenous and dietary selenium examined in brain, liver, and kidney.

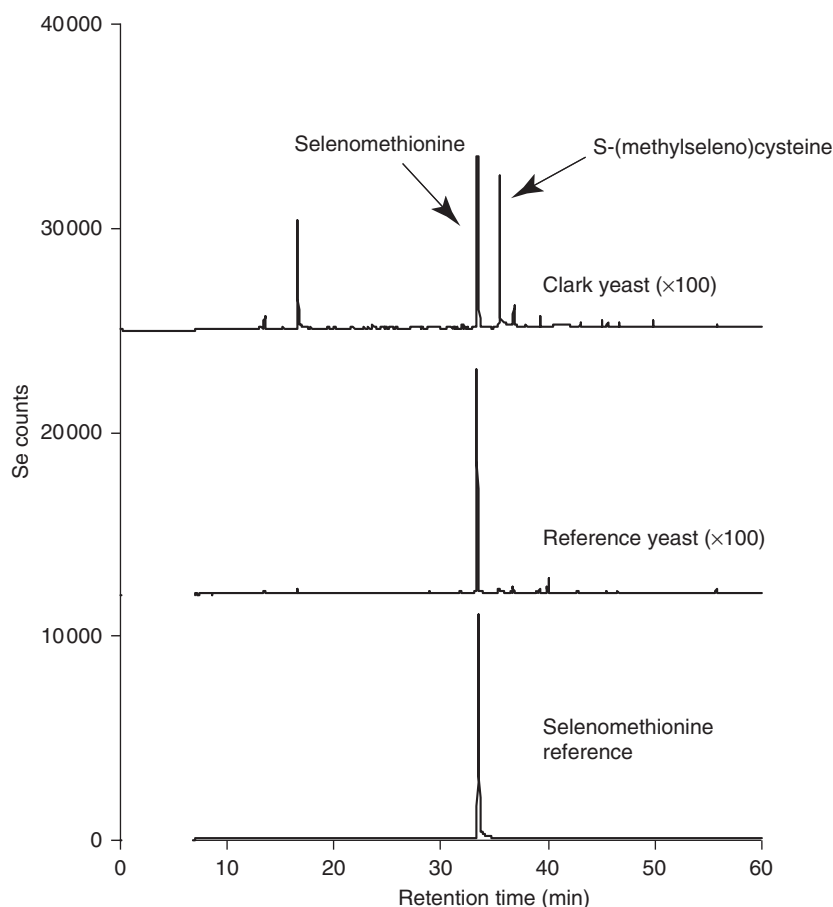

#### **Chiral Speciation of Selenium Species by HPLC-ICP-MS**

The presence of asymmetric carbons in selenomethionine, other  $\alpha$ -selenoamino acids, and related compounds produces different chiral enantiomers with different physiological activities. HPLC separation of enantiomers is possible with a range of chiral stationary phases. d- and l-Selenomethionine enantiomers have been resolved with an  $\alpha$ -cyclodextrin stationary phase and other species with a teicoplanin-based chiral phase. Hybrid chiral methodologies based on GC, HPLC, and capillary electrophoresis, coupled with ICP-MS are feasible. Enantiomers of d,l-selenocystine, d,l-selenomethionine, and d,l-selenoethionine were examined in a range of commercial dietary supplements using a chiral crown ether stationary phase and ICP-MS detection. Selenium-enriched onion, garlic, and yeast were analyzed and some of the selenoamino acid enantiomers were identified. 1-Fluoro-2, 4-dinitrophenyl-5-l-alanine amide was used to derivatize enantiomers of selenoamides for enhanced resolution.

#### **Microwave Plasma Atomic Emission GC Detection of Selenium**

Gas chromatography interfaced with atomic plasma emission spectroscopic detection (GC-AED) is an established tool for specific element detection of volatilizable species and has been used to detect and determine many volatile organoselenium compounds present in or produced by plants. Headspace-GC-AED is used to detect selenium compounds in members of the *Allium* family such as garlic, elephant garlic, onion, and broccoli (*Brassica*). A common structure is  $R-S_x(Se_y)-R'$ , where the R and R' are methyl or allyl groups and x or y may be 1–3. Natural abundance organoselenium compounds in human breath after ingestion of garlic can be identified using Tenax trap/cryogenic-GC-AED.

Free selenoamino acids, selenocysteine, Se-methyl selenocysteine, and selenomethionine in normal and selenium-enriched plants may be determined by GC-AED of ethylated derivatives. AED, flame photometry, and GC-MS detection have been compared for selective determination of selenomethionine in wheat samples.

**Figure 3** Selenium-specific GC-AED chromatograms (Se 196 nm) of ethylated enzymatic hydrolyzates of archived 200 µg Se tablets (top), reference 200 µg Se tablets (center), and selenomethionine (bottom). Peak at ~36 min contains sulfur also.

Selenomethionine is the predominant selenium moiety in plants whereas selenocysteine is probably formed from glycine and selenite in mammalian tissues. Analytical approaches are typically based on degradation of the original matrix to these and other amino acids followed by their determination. For this purpose, GC with element-selective or mass spectrometric detection provides a valuable alternative to HPLC due to improved sensitivity. Selenoamino acids are derivatized with isopropylchloroformate and bis(*p*-methoxyphenyl) selenoxide, and with ethyl chloroformate. **Figure 3** shows comparative selenium-specific GC-AED chromatograms for ethylated extracted enzymatic yeast hydrolyzates of archived selenized yeast employed in the ‘Clark trial’, a reference fresh selenized yeast and reference selenomethionine.

### GC with ICP-MS Detection

Although less widely adopted than HPLC–ICP-MS, GC–ICP-MS can fulfill some of the same speciation

functions as GC-AED for selenium. Selenomethionine enantiomers were resolved by capillary GC as trifluoroacetyl-*O*-isopropyl derivatives with a *l*-valine-*tert*-butylamide modified chiral stationary phase, detection limits below 250 pg being obtained for each isomer with ICP-MS. A glow discharge (rf-GD) mass spectral ion source was used as a sample introductory technique for selenoamino acids, with detection limits of 100 pg being seen for derivatized selenomethionine.

### Capillary Zone Electrophoresis with ICP-MS Detection

Capillary zone electrophoresis (CZE) is an effective technique for the definitive verification of the chromatographic purity of the target compound because of the large number of theoretical plates obtainable. The advantages of CZE, such as the possibility of analyzing for relatively labile species because of the absence of chromatographic packing, must be

considered given the need for ultrasensitive detection, such as high-resolution ICP-MS because of the small sample amount injected. A commercial interface for CZE-ICP-MS is available that optimizes electrophoretic and nebulizer flows and has minimal dilution and sample consumption.

The potential of CZE-ICP-MS has been particularly realized in the identification and determination of selenogluthathione and differentiation of methionine, selenomethionine, cystamine, and selenocystamine in milk. Se(IV), Se(VI), selenate-carrying glutathione (GSSeSG), selenomethionine, selenocystine, and selenocystamine can be speciated at the 10–50 µg per Se per liter level. A two-dimensional separation approach for selenized yeast speciation, based on size exclusion followed by CZE-ICP-MS, coupling to the ICP via a self-aspirating total consumption nebulizer affords limits of low molecular weight selenium species in the range 7–18 µg l<sup>-1</sup>.

## Mass Spectral Structural Identification

HPLC-ICP-MS, GC-AED, and CZE-ICP-MS offer sufficient sensitivity and selenium selectivity for the speciation of selenium compounds in many samples but do not give structural identification of known, unknown, or unpredicted compounds. This lack of identification becomes more important as more efficient separations are achieved. Chromatographic identification is based on migration time through a chromatographic support, but authentic standards of selenium compounds are often not available for retention-based identification, except for simple compounds. The major approaches to analyte authentication involve preparation of additional synthetic standards or isolation of purified selenium compounds from sample matrixes for further characterization by electrospray (ES-MS) or matrix-assisted laser desorption ionization.

The identification of selenium species by matching retention (migration) times with those of authentic standards demands the assurance that the resolution of the chromatographic technique produces at a given retention time a signal corresponding to this compound only, and that peak shapes are not distorted by sample overload or unacceptable adsorption. Thus, hyphenated molecular characterization by MS or NMR spectroscopy provides valuable confirmatory data for chromatographic speciation of standards and identifications of unknowns.

A combination of two-dimensional multinuclear NMR, electrospray MS, and GC-MS methods is valuable to characterize Se-methylselenomethionine, Se-methylselenocysteine, and dimethylselenonium

propionate in synthetic preparations. GC-MS is sensitive but restricted to volatilizable species; for the nonvolatilizable metabolites, there is often a discrepancy between the sensitivity of HPLC-MS techniques and that needed for speciation in real samples. For real-world samples, purification and preconcentration of selenium species are usually needed.

Electrospray MS that allows a precise ( $\pm 1$  Da) determination of molecular mass is an invaluable tool for the identification and a prerequisite for further characterization of compounds in speciation analysis. ESI-MS has been applied mostly to commercial standards or synthetic preparations. Pneumatically assisted ESI-MS is used to identify Se-adenosylhomocysteine in an extract of selenized yeast. Selenium in garlic has been speciated by parallel ICP-MS and electrospray tandem MS. A novel selenium metabolite in rat urine, the selenosugar diastereomer Se-methyl-N-acetylhexosamine, has been identified by this method. It should be emphasized that when authentic standards are not available the use of tandem MS is vital to confirm selenium speciation indicated by means of hyphenated selenium-specific detection.

## Introduction

Sensor research has always been a very dynamic area. We have gone a long way since the primary form of sensor, litmus paper, was first made for crude pH measurements. Since the mid-1980s, there has been an explosion of research interests in sensor development as witnessed by the overwhelming amount of papers published during this period.

Sensor research has always been driven by commercial needs. It is also an area that crosses over several developing areas, and has benefited by the advances in material sciences, engineering, and

affordable computer technology. Consequently, in recent years, there is huge diversity of sensors available in the market place that covers industrial, environmental, and clinical applications. Yet, despite the large amounts of capital and human resources invested in the development of new devices, the best sensor commercially available is probably still the pH glass electrode in terms of its selectivity, sensitivity, dynamic range, response time, robustness, and ease of manufacture. The big successes in commercial terms since the late 1950s have been, in the chemical sector, the oxygen electrode based on the Clark cell, the fluoride electrode and ion-selective electrodes (ISEs) used in clinical analyzers, and the solid-state oxygen sensors based on zirconium oxide ( $\text{ZrO}_2$ ) and titanium oxide ( $\text{TiO}_2$ ) used in automobile air-to-fuel control; whereas more recently in the biosensor sector, the various glucose sensors based on glucose oxidase and the pregnancy test strips have been successful. There are clear advantages in using sensors in field (or *in vitro*) applications compared to

## Introduction

Sensor research has always been a very dynamic area. We have gone a long way since the primary form of sensor, litmus paper, was first made for crude pH measurements. Since the mid-1980s, there has been an explosion of research interests in sensor development as witnessed by the overwhelming amount of papers published during this period.

Sensor research has always been driven by commercial needs. It is also an area that crosses over several developing areas, and has benefited by the advances in material sciences, engineering, and

affordable computer technology. Consequently, in recent years, there is huge diversity of sensors available in the market place that covers industrial, environmental, and clinical applications. Yet, despite the large amounts of capital and human resources invested in the development of new devices, the best sensor commercially available is probably still the pH glass electrode in terms of its selectivity, sensitivity, dynamic range, response time, robustness, and ease of manufacture. The big successes in commercial terms since the late 1950s have been, in the chemical sector, the oxygen electrode based on the Clark cell, the fluoride electrode and ion-selective electrodes (ISEs) used in clinical analyzers, and the solid-state oxygen sensors based on zirconium oxide ( $\text{ZrO}_2$ ) and titanium oxide ( $\text{TiO}_2$ ) used in automobile air-to-fuel control; whereas more recently in the biosensor sector, the various glucose sensors based on glucose oxidase and the pregnancy test strips have been successful. There are clear advantages in using sensors in field (or *in vitro*) applications compared to

conventional analytical instruments and therefore the search for better performing and cheaper sensors will always interest the researchers in both the industrial and academic worlds.

This article will concern itself only with devices that involve a chemical or biochemical transduction mechanism to generate the analytical information, with the processes occurring in a membrane or layer attached to the probe in such a manner that the analytical information can be accessed electronically from the outside world. This covers sensors that are for single use and for continuous monitoring because the basic chemistry and sensor configuration used are very similar for a particular application. Hence, the article does not cover techniques such as open-cell Fourier transform infrared or remote fiber spectroscopy, which can be used to 'sense' the chemical nature of the environment without involving the use of a bona fide sensor.

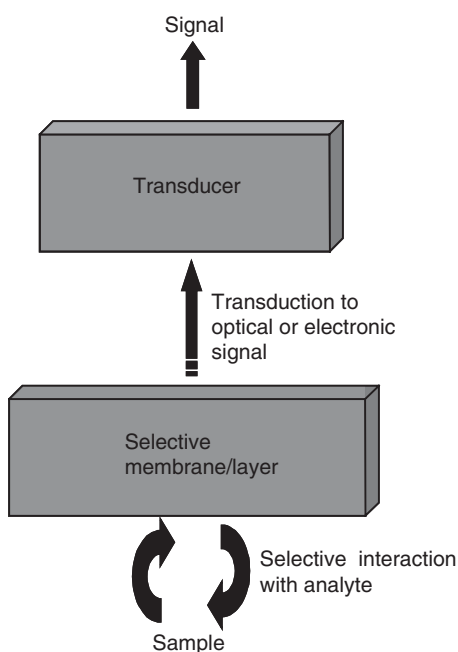

## Signal Generation

Figure 1 is a schematic representation of the main components of an idealized chemical sensor. The most important part of any chemical sensor is the selective membrane/layer, usually positioned on the sensor tip, which interacts with the sample in such a way as to provide analytically useful information about a particular component, the analyte, in the sample. In order to do this, the interaction of this

membrane/layer with the sample must be selective, i.e., it must be able to distinguish the analyte from the sample matrix. This is achieved by immobilizing receptor sites for the analyte species in the membrane/layer. Many different mechanisms have been used to achieve the required selectivity:

- ion-cavitand 'best-fit' interaction;
- electrostatic interactions;
- acid–base reaction;
- redox reaction;
- antibody–antigen interactions;
- enzyme–substrate reaction;
- ion-exchange reactions.

Generally, a membrane is configured in such a way that the selective chemical process or processes occurring at the membrane–sample boundary are coupled to a transducer using either electronic or optical means in order to make the signal accessible. This signal consists of an analytically useful component (i.e., related to the amount of analyte in the sample) in association with a component that does not convey useful information. The latter component can be subdivided into random noise, experimental errors, and errors arising from contributions from other species in the sample matrix to the signal (interferents). This component is minimized by maximizing the selectivity of the sensor, or by maintaining its contribution at a fixed level using techniques such as standard addition.

**Figure 1** Generalized scheme of the main elements of a sensor.

## Advantages of Sensors over Instrumental Methods

Although results obtained from sensor-based analytical methods are becoming more precise and accurate, instrumental methods are generally superior. However, sensors find their niche in applications that involve field measurements, measurements in remote or inaccessible places (e.g., *in vivo* monitoring), or where dictated by balancing cost against the degree of precision and accuracy required (sensor-based measurements are generally cheaper, and can be easily automated). Perhaps most importantly, sensors can often provide information as to how the target species concentration varies in real time, a function that is usually not available from analytical instruments.

## Sensor Characteristics

The ideal sensor should possess the following characteristics:

(1) 'Specificity for the target species'. This means that fluctuations in the signal obtained can be

unambiguously assigned to the target species. The function relating the response ( $S_i$ ) to the analyte concentration ( $C_i$ ) ideally should be linear, or easily linearized (although improvements in data processing have relaxed this constriction somewhat), i.e.,

$$S_i = M_i C_i + b_i \quad [1]$$

where  $M_i$  is the slope of the response function (selectivity) and  $b_i$  is the intercept on the signal axis.

In reality, sensors are selective rather than specific, and respond to greater or lesser degree to other chemical or biological species ( $j$ ) present in the sample:

$$S_i = M_i C_i + b_i + \sum_{j \neq i} K_j C_j \quad [2]$$

where the summation factor above incorporates the contribution of all interfering species ( $j$ ) along with a weighting coefficient  $K_j$ . In the ideal sensor, these coefficients are all zero, leading to a specific response to the analyte ( $i$ ) only.

A large amount of sensor research has been investigated in developing more selective sensors in order to minimize the error arising from the summation factor above, and to devise efficient methods for quantifying selectivity, so that the limitations of applicability of a particular device can be clearly identified. This is still a key area of research at present for most types of sensors. In addition to improving the selectivity of individual sensors, the use of arrays of sensors and advanced data-processing techniques has led to enhancements in selectivity through interpretation of the patterns obtained. With a multivariate approach, the sensor response characteristics are modeled, and the weighting factors for important interferences determined for each sensor in the array. This modeled error can then be subtracted from the analytical signal to give more accurate results.

(2) ‘Sensitivity to changes in the target species concentration’. The response slope ( $M_i$  in eqn [1]) of the sensor should be as large as possible to enable very small changes in the target species concentration to be detected. In some cases, it is possible to enhance the sensitivity by coupling the selective membrane interaction between the sensor and the analyte with further reactions (chemical amplification).

(3) ‘An extremely fast (instantaneous) response time’. This enables high-speed fluctuations in the analyte concentration to be monitored. For many applications, time constants of up to a few second can be tolerated.

(4) ‘An extended lifetime of at least several months’. This can be a major problem, particularly with biosensors based on enzyme or antibodies due to

gradual denaturation in the former and irreversible interactions in the latter. However, devices such as the glass electrode and other ISEs can have lifetimes extending into years when used carefully.

(5) ‘Small size and manufactured to high precision’. The integration of semiconductor manufacturing technologies with sensor fabrication is already an important aspect of the present sensor preparation techniques. These devices are generally small, solid state, well characterized, and identical in performance. These sensors have found their places in disposable sensor market and have important contributions to the progress into the use of sensor arrays rather than single devices. Advances in the areas of electronics and computing will enable powerful signal processing facilities to be made available in small palm-top instruments linked to the sensor arrays.

## Types of Sensors

It is possible to categorize sensors in many different ways including the mode of transduction (as in this case), the application (clinical sensors, gas sensors), or the size (nano, micro, mini, macro, industrial, bench-type sensors, etc.). The main differences in terms of operation and mode of transduction are summarized in Table 1.

### Electrochemical

#### Potentiometric

*Ion-selective electrodes* This is a classical field of chemical sensors, which bridges multidisciplinary research areas of host–guest chemistry, engineering, and material (membrane) science. In these devices, the selective membrane is symmetrically bathed by two electrolyte solutions, the internal reference solution and the external sample solution. The potential of an ISE is monitored with respect to an ideally invariant potential generated by a reference electrode under equilibrium conditions (i.e., zero current). Changes in the cell potential are related to the composition of the sample solution via the Nernst and Nicolsky–Eisenmann equations, which predicts a logarithmic relationship with the analyte or primary ion activity. While the logarithmic scale often leads to wide dynamic ranges for ISEs (typically four to five orders of magnitude, and up to 12 orders of magnitude with the glass electrode and the recently improved low detection limit ISEs), the fact that a rather vague thermodynamic quantity (activity) is monitored rather than concentration has led to difficulties in certain areas of application.

**Table 1** Sensor types classified by mode of transduction

<i>Sensor type</i>	<i>Chemical process involved</i>	<i>Parameter monitored</i>	<i>Conditions under which measurement is made</i>
Potentiometric	Spontaneous processes, e.g., movement of ions into membranes	Cell potential ( $E$ )	Zero current, i.e., equilibrium
Amperometric	Electrochemical reactions driven by an external potential	Limiting current $I_l$	Constant external potential ( $E$ )
Piezoelectric	Movement of material into or out of a surface or layer	Change in mass	External AC signal
Thermal	Any process involving a change in enthalpy ( $\Delta H$ )	Change in enthalpy	No heat transfer to surroundings
Optical	Any process resulting in a change in the optical properties of the immobilized selective membrane	Absorbance, fluorescence, refractive index, etc.	Detector must be shielded from extraneous radiation

The oldest, and still the best, ISE is the glass electrode, which was commercialized by the late 1920s. The introduction of poly(vinyl chloride)/neutral carrier membranes in the early 1970s led to a series of devices for cations ( $H^+$ ,  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Mg^{2+}$ ,  $Ba^{2+}$ ,  $Cs^+$ ,  $NH_4^+$ ,  $Ag^+$ ) and anions ( $NO_3^-$ ,  $Cl^-$ ,  $HCO_3^-$ ). Solid-state ISEs (coated wire electrodes) have also been developed in which the sensitive membrane is coated directly onto a metal wire, usually a silver–silver halide. While these have the advantage of being small and easy to fabricate, they have been noted for their unpredictable properties and suffer from lifetime and stability problems. More sophisticated approaches involve the use of semiconductor planar fabrication technologies to deposit ion-sensitive layers onto semiconductor substrates to produce ion-selective field-effect transistors. These are conceptually very attractive but it has proven very difficult to produce devices as good as the equivalent ISE.

Solid-state (crystalline) devices have also proven successful, particularly with respect to the excellent fluoride electrode, and to a lesser extent with devices based on silver sulfide and related substances ( $Ag^+$ ,  $Cu^{2+}$ ,  $Cd^{2+}$ ,  $Pb^{2+}$ ). Potentiometric biosensors incorporating enzymes and antibodies have also been reported. In these devices, the biological reaction either consumes or produces a species that can be monitored by an ISE directly (commonly  $H^+$ ,  $NH_4^+$ ), or it is coupled with a second reaction. Examples include a sensor for glucose, which utilizes the coupling of the oxidation of glucose by glucose oxidase with the activity of the fluoride ions through the action of a second catalytic reaction on an organofluorine compound, and similar sensors for urea, penicillin, malate, asparagines, and sucrose. In a similar manner, a range of gas sensors have been produced that enable the gas to be monitored via the interaction of the gas with a buffer solution immobilized at the sensor tip by means of a gas permeable

membrane. Most involve the use of hydrogen ion-selective electrode and a pH buffer. Suitable gases include sulfur dioxide, carbon dioxide, ammonia, amines, and other acidic and basic gases. In addition, many devices have been reported that employ an ion-pair approach to enable ionizable drugs or organic ions such as histamine, nicotine, heroin, phenylephrine (cations) and carboxylates, amino acids, bile acids, and valproate (anions) to be monitored.

ISEs represent a mature sensor technology based on well-understood mathematical principles. Up until recently, the research areas have been mainly focused on applications rather than fundamental research. However, this research field has reinvented itself and a number of new and important research directions have emerged. The ongoing research to develop more efficient ionophores and also to expand the range of ions that can be successfully monitored are: the use of new membrane materials with low glass transition temperatures to eliminate the use of plasticizers and the use of redox membrane materials (e.g., polypyrrole) that act as ion-selective membranes and the solid contact at the same time; the studies of nonclassical response mechanisms; and, more significantly, the investigations and eventually breakthrough in obtaining low detection limits to picomolar levels, resulting in a class of very inexpensive sensors with detection limits comparable to inductively coupled plasma-mass spectrometry.

**Amperometric sensors** In contrast to potentiometric measurements where the monitored parameter, the cell potential, arises from spontaneous reactions, in amperometry the cell reaction is driven by an external fixed potential, and the current is monitored. With these sensors, in the idealized ‘specific sensor’ case, the signal resulting from a redox reaction is proportional to the concentration of the analyte species. Cells can be either two-electrode (working and reference) or three-electrode (working, counter, and

reference) systems, with the latter being introduced to circumvent problems arising from drawing current through the reference electrodes.

Electrochemical biosensors or electrochemical sensors for monitoring biologically important species are the fastest developing area of this sensor field. There are now commercially available devices for clinical, food, and environmental applications. Suitable target species for amperometric sensors are thus electroactive species (i.e., capable of being oxidized or reduced electrochemically), with the oxidation/reduction potential being as near zero volts as possible, as the number of possible interferents will increase with the magnitude of the external potential.

The best-known amperometric sensor is the Clark oxygen cell, developed by Clark in 1956. A wide range of biosensors have been reported in the literature in which the concentration of an enzyme substrate is measured indirectly through the consumption of oxygen by oxidase-catalyzed reactions or, in a similar manner, by the generation of hydrogen peroxide, i.e.,

where S = substrate and P = products.

In most of these, the bioselective layer is deposited directly on the surface of a Clark-type working electrode using a variety of designs and immobilization techniques. While oxygen and hydrogen peroxide can be monitored successfully by polarizing the working electrode at  $-0.7\text{ V}$  or  $+0.7\text{ V}$ , respectively, the high potentials used leave the measurements open to interference from other redox-active species in the sample. In addition, the successful application of this approach depends on a sufficient oxygen supply, which can be problematic at high substrate concentration. To overcome these problems, there has been great interest in the development of efficient mediators that can shuttle electrons from the enzyme-catalyzed reaction through to the electrode surface at moderate external potentials. Molecules such as ferrocene and its derivatives, hexacyanoferrate(II)/(III) and benzoquinones, have been successfully used in this context, by coimmobilization in the bioselective layer. Attention has also been focused on the development of activated carbon paste electrodes, normally doped with small metal particles such as palladium, which functions as catalyst to reduce the overpotential required for hydrogen peroxide detection.

The most successful amperometric sensor in the 1990s is probably the various diabetes home care systems based on glucose sensor strips. These enzyme

electrodes are principally similar and are based on enzymatic reactions where a mediator is used for signal generation, i.e.,

where P = products.

Selectivity in these devices can be optimized through selection of moderate operating potentials, the use of enzymes that will selectively oxidize or reduce the analyte, or through selective control of mass transport via an additional outer permselective membrane. Mechanisms that have been used for this purpose include size (hydrolyzed cellulose acetate) and charge (Nafion<sup>TM</sup>) exclusion.

A major problem with all types of biosensor, and antibody-based devices in particular, is the short lifetime and irreversibility of the reactions involved. For monitoring purposes, it is just as important for the signal to return to baseline after a transient increase in the signal, as it is to detect the increase itself. This requires that the chemical processes in the sensor membrane that generate the observed signal should be fast and reversible, with stability constants ( $\log \beta$ ) for products typically lying in the 5–6 range. Most antibody-based reactions have stability constants many order of magnitude in excess of this, and regeneration of the original layer (i.e., removal of the substrate) usually requires extreme conditions that effectively destroy the biomembrane. Hence, reversibility is a major and continuing problem with many biosensors, and the subject of intensive research at present.

Various approaches have been investigated for immobilizing the bioreagents including direct covalent linkage, physical entrapment using porous membranes or hydrogels, incorporation into Langmuir–Blodgett (L–B) films, cross-linking with collagen and other cross-linking agents, and molecular wire approach where the enzyme is covalently attached to a redox polymer. Miniaturization has become an important research area especially for *in vivo* sensing. These small implantable electrodes modified with specific coatings are useful for online monitoring of very low concentration metabolites such as dopamine, nitric oxide, and insulin as well as important analytes such as glucose and ascorbate. Major problems still exist in the area of *in vivo* clinical monitoring including biocompatibility, stability, selectivity with respect to other matrix components such as drugs administered during therapy, and calibration.

## Optical Sensors

The development of inexpensive, efficient fiber-optic cables for applications in telecommunications and technological advances in the semiconductor sector has together stimulated much research into optical sensors. Typically, these devices incorporate a material at the tip or on the side of the cable (evanescent wave devices), which can generate an optical signal related to the concentration of the target species in the sample. Both fluorescence and absorbance have been used for this purpose, via both direct and indirect mechanisms. The fluorescence method has attracted much interest in recent years due to its superior sensitivity and low volume required. An important advantage of fluorescent measurements over absorbance/reflectance measurements is that it is possible to measure the fluorescence lifetime instead of intensity, therefore minimizing problems such as turbidity and ambient light associated with intensity-based measurements. The dual lifetime referencing scheme for converting fluorescence intensity into frequency domain or time domain has since been developed to include two fluorescent dyes, one active and the other inert to act as a reference. These systems provide a unique means to referencing the optical signal against background interferences including drifts resulting from optoelectronic components.

Various methods have been used for immobilizing the optically responsive material including physical entrapment with permeable layers and incorporation into L-B and sol-gel films. Sensors for hydrogen and other ions is a popular topic for research, and much activity continues in the design and synthesis of new materials and cocktails for these optodes. This can be achieved by functionalizing ionophores with ionizable chromophors or fluorophores or by arranging reactions that involve deprotonation of a chromophore to charge compensate the sequestering of the cation from the sample phase by the ionophore. Attachment of biological functionalities to molecular building blocks that incorporate fluorophores is an attractive proposition for the development of new types of immunoassays in particular. Reversibility is once again the key obstacle. Optical sensors for many gases including oxygen, ammonia, carbon monoxide, chlorine, anesthetics, and volatile organic compounds (VOCs) have also been described.

Another area of growing importance in optical sensing is the surface plasmon resonance (SPR). This technique makes use of the surface plasma wave (SPW) that may exist at the interface of two media with dielectric constants of opposite signs, e.g., a metal and a dielectric. The excitation of the SPW by

an optical wave results in resonant transfer of energy from the incident light into the SPW. This gives rise to resonant absorption of the energy of the optical wave to manifest SPR. Variations in the optical properties of the dielectric (the transducing medium) adjacent to the metal layer induce changes in the propagation constant of SPW. This change of optical parameters in the dielectric therefore can be detected by monitoring the interaction between the SPW and the optical wave.

The main feature of the SPR optical system comprises a radiation source and an optical structure where the changes in optical properties of the transducing medium, normally modified with specific (bio)chemical receptors, is interrogated. As the propagation constant of SPW is always higher than that of optical wave propagation in the dielectric, in order to excite SPW efficiently the momentum of the incident light is enhanced to match that of the SPW by using techniques such as diffraction at the surface of diffraction grating and attenuated total reflection in prism couplers and optical wave guides. The detection approaches commonly used are measurement of the intensity of the optical wave near resonance, and measurement of the resonant momentum of the optical wave including angular and wavelength interrogation of SPR. The applications of SPR are diverse and include the study of optical properties in metal films, film thickness, and refractive index measurements of organic layers on metal surfaces, protein adsorption to biomolecules, and the adsorption of gas molecules. Utilizing SPR as a biosensor has led to the first commercial SPR biosensor (BIAcore) launched in 1990. Since then increasing number of SPR systems employing different sensing approaches have been made available.

The main disadvantages of SPR-sensing devices are their lack of sensitivity when monitoring low molecular weight adsorbates and the limited use in kinetic analysis due to slow mass transport. These are still important directions for SPR sensor research and much effort is still being put in enhancing sensitivity and the study of nonspecific biomolecular interactions. On the instrument side, research into miniaturization and multichannel approach for high throughput analysis are emphasized.

## Mass Sensors

In these relatively new sensors, an acoustic wave is propagated by an externally applied alternative current between two electrodes or interdigitated electrodes deposited on a piezoelectric substrate such as quartz. There are several subclasses of piezoelectric transducers (bulk wave, surface acoustic wave, or

flexural plate wave) based on the way the acoustic wave is propagated between the electrodes. The fundamental frequency of the acoustic wave depends on the surface loading of the crystal, enabling these devices to function as very sensitive microbalances. Coating the crystal surface with a material, which will selectively interact with a sample phase, either liquid or gaseous, can induce a selective response. The increase in fundamental frequency obtained is simply related to the increase in mass in the surface layer, which in turn may be related through appropriate calibration to the bulk sample concentration.

Most applications for these devices have been for gas-phase monitoring, although recently, aqueous-phase applications are receiving more attention (glucose, immunosensors). In gas phase, hydrogen sulfide, carbon dioxide, oxygen, nitrogen dioxide, molecular hydrogen, mercury, formaldehyde, VOC sensors have been fabricated. A major problem has been the response of these transducers to humidity, which means that the humidity must be controlled or else compensated for with a reference transducer in different mode measurements. Selectivity has been another problem, although the use of arrays of piezoelectric sensors with different coatings and pattern recognition techniques can improve the situation markedly.

Specialized designs are available that enable acoustic sensors to be used as the working electrode in a voltammetric cell. This enables exciting fundamental experiments to be performed, where the mass changes during a voltammetric scan can give important insight into the mass transfer processes occurring at the electrode surface, although, as with any new technique, the results have to be interpreted with great care.

### **Calorimetric (Thermal) Sensors**

Almost every reaction that occurs is accompanied by a change in enthalpy, which can be measured as a rise or fall in temperature in adiabatic systems of known specific heat capacity. Furthermore, the reaction of interest can often be coupled with other reactions that can amplify the enthalpy change, a common example being enzyme-catalyzed reactions that involve a proton exchange being performed in tris(hydroxymethyl)aminomethane buffer.

The best known of these are the enzyme thermistors. Thermistors are devices whose resistance changes markedly with temperature and consequently are often employed as inexpensive, sensitive temperature sensors. In early designs, the matched thermistors were sited in a flow system downstream of packed enzyme and reference columns. Interaction

of enzyme with the substrate in the flowing stream produced a temperature change, which could be related to the concentration of substrate in the sample. More recently, the enzyme coating has been applied directly to the thermistor surface, with glucose once again being the most common substrate targeted. New sensors based on pyroelectric materials are revitalizing this rather dormant area of sensor research.

## **Sensor Developments**

### **Miniaturization and Arrays**

There is increasing interest in fabrication technologies that will enable miniaturized versions of conventional sensors to be produced with very reproducible characteristics. This will accelerate the trend toward the use of sensor arrays rather than the traditional standalone approach. Arrays can give much more information than the sum of individual components, and through self-diagnostics, the application of pattern recognition techniques, and rigorous calibration regimes, the information will be much more dependable and robust. Analysts have gradually adopted these methods as the instrumentation required for multichannel data collection is readily available; they are normally equipped with data collection/chemometric analysis software. The more robust and flexible methods offered by using arrays help to stimulate commercial activity that will in turn generate more finance for research. Sensor design is moving rapidly from the traditional, hand-assembled bench electrodes that have been the norm for the past 50 years or more, to planar technologies developed by the semiconductor industries. Deposition techniques such as vapor deposition, sputtering, screen printing, ink and bubble-jet printing have become standard technologies to place the correct amount of active components in micro- and miniaturized sensors in exactly the right place on the substrate.

### **Materials**

Materials research has been influencing the direction and diversity of sensor research. Novel semiconductor and superconductor materials have led to new and more efficient transducers. Advances in biotechnology have also resulted in a broader range of enzymes and monoclonal antibodies for use in biosensors. Examples for utilizing tissue and microbes in biosensors include the use of tomatoes, eggplant, grapes, horseradish, parsley, and Antarctic krill in electrochemical biosensors. The logic is that the active component (usually an enzyme) is protected by

the microenvironment offered by the tissue and can thus function for a longer time compared to the more expensive purified enzyme. Supramolecular chemistry is becoming a very lively area in synthetic research. Crown ethers, calixarenes, cavitands, and molecules with similar ion-complexing properties are now being used as the building blocks of more sophisticated structures containing chromophores, ionophores, and enzymes/antibodies. The possibility exists of producing molecules that can generate information by optical or electrochemical transduction of the same chemical process. Chemists are now calling some of these substances 'designer' molecules as the receptor-site morphology can be modeled using three-dimensional computer graphics in order to give a 'best fit' for the target species.

### Flow Injection Analysis

The coupling of sensors with flow injection analysis (FIA) is already a very popular option. The flow regime offers important advantages over discrete manual measurements that include (1) Sample preparation: processes such as reagent mixing, selectivity enhancement (e.g., removal of large molecular mass interferents such as protein by dialysis in clinical assays), and solvent extraction can all be carried out online. The improved sample preparation and more reproducible sample delivery result in improved measurement precision and accuracy. Drift is less of a problem as measurements are made of peak heights relative to a baseline. (2) Improved sensor lifetime: in flow analysis, the sensor may be exposed to the sample for only a short period of time, and maintained in a friendlier matrix between measurements that can help counteract or delay the deleterious effects of the sample. (3) Automation: the entire analysis can be

automated. Valves, samplers, and peristaltic pumps can be easily controlled from a personal computer. Flow speed and direction of flow can be controlled with very high precision and accuracy. Very high sample throughputs can be achieved, with more than 100 assays per hour being regularly reported. Furthermore, the combination of sensor arrays, sophisticated data processing, and FIA offers high levels of precision and accuracy in analysis coupled with almost instantaneous feedback (results are generated typically in 30–60 s).

### Introduction

The determination of oxygen, mainly in dissolved form in aqueous samples, is by far the largest field of application for amperometric sensors. Because of their reliability, ease of use, and the fact that results are available almost instantaneously, these devices are widely used.

### Principles

Amperometric sensors are small electrochemical cells consisting of two or three electrodes that are usually combined in a single body. A constant potential is applied, i.e., the sensor operates as a Faradaic cell, and a dependence of the measured current on the analyte concentration in the sample is obtained. As in ordinary amperometry, this requires a diffusion layer on the surface of the working electrode. This diffusion layer, in which the analyte concentration is depleted, arises because the analyte is consumed in the electrode reaction. In order for this depletion to occur, the electrode kinetics has to be faster than the

the microenvironment offered by the tissue and can thus function for a longer time compared to the more expensive purified enzyme. Supramolecular chemistry is becoming a very lively area in synthetic research. Crown ethers, calixarenes, cavitands, and molecules with similar ion-complexing properties are now being used as the building blocks of more sophisticated structures containing chromophores, ionophores, and enzymes/antibodies. The possibility exists of producing molecules that can generate information by optical or electrochemical transduction of the same chemical process. Chemists are now calling some of these substances 'designer' molecules as the receptor-site morphology can be modeled using three-dimensional computer graphics in order to give a 'best fit' for the target species.

## Amperometric Oxygen Sensors

**P C Hauser and S S Tan**, The University of Basel, Basel, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

The determination of oxygen, mainly in dissolved form in aqueous samples, is by far the largest field of application for amperometric sensors. Because of their reliability, ease of use, and the fact that results are available almost instantaneously, these devices are widely used.

### Principles

Amperometric sensors are small electrochemical cells consisting of two or three electrodes that are usually combined in a single body. A constant potential is applied, i.e., the sensor operates as a Faradaic cell, and a dependence of the measured current on the analyte concentration in the sample is obtained. As in ordinary amperometry, this requires a diffusion layer on the surface of the working electrode. This diffusion layer, in which the analyte concentration is depleted, arises because the analyte is consumed in the electrode reaction. In order for this depletion to occur, the electrode kinetics has to be faster than the

rate of transport of the analyte to the electrode surface. For a linear dependence of current on concentration it is also essential that the transport through this depletion layer is by diffusion only and not by either of two other possible processes: electrostatic migration and convection.

The flux of the analyte to the electrode surface and therefore the current can be derived from the diffusion coefficient and the concentration gradient using Fick's law of diffusion. It is usually possible to employ the so-called Nernst approximation where the concentration ( $c$ ) is taken to linearly decrease from a certain distance ( $\delta$ ) where the concentration corresponds to the bulk of the sample ( $c_\infty$ ) to a concentration of zero on the electrode surface itself. This situation is illustrated in **Figure 1**.

The current is then given by the following combination of Fick's law of diffusion and the Faraday equation:

$$i = nFD \frac{c_\infty}{\delta} \quad [1]$$

where  $i$  is the measured current,  $n$  the number of electrons exchanged in the redox reaction,  $F$  the Faraday constant, and  $D$  the diffusion coefficient. From this it follows that the current is linearly dependent on the concentration in the bulk of the solution.

For ordinary amperometry in solution, the diffusion layer is formed as part or all of the stagnant or nonstirred layer of liquid that exists on solid surfaces. This layer does not take part in convection processes and therefore any flux of material through it is solely by diffusion. The thickness of the stagnant layer of the solution is determined by the flow velocity of the solution across the surface and therefore by the rate of stirring, the flow rate of the liquid, or the movement or rate of rotation of the electrode. If the diffusion layer extends over the entire thickness of the stagnant layer, then these flow parameters affect the performance of the cell. In amperometric sensors a membrane usually separates the working electrode from the sample solution. Often, the diffusion layer is largely confined to this membrane, so that the flow rate dependence is strongly reduced or even eliminated.

### Current/Voltage Behavior

A typical response of an amperometric cell is illustrated in **Figure 2**. On increasing the voltage, a rise in current is obtained when the redox potential of the species sensed is reached. A current plateau is reached for the diffusion limited case as discussed above, since this transport process is independent of the applied voltage. If the voltage is increased further,

**Figure 1** Concentration profile at an electrode according to the Nernst approximation.  $c_\infty$  is the concentration in the bulk of the sample and  $\delta$  the distance from the electrode to which the concentration is depleted.

**Figure 2** Current ( $i$ ) versus voltage ( $E$ ) plot obtained in amperometry for a cathodic reaction. The plot shows the rise of the current when the reduction potential of the analyte is reached, the plateau region, and the final increase in current resulting from the reduction of an interfering species or the solvent.

a different reaction such as the reduction or oxidation of a secondary species in the sample or eventually the decomposition of the solvent will set in. It is important that the plateau for the analyte is relatively wide so that the sensor is not sensitive to small changes in the applied voltage. Some discrimination against interferences can be obtained by choosing an appropriate potential. This, however, does not allow suppressing species that are reduced or oxidized at lower potentials than the analyte. The selectivity may be improved by the elimination of an interferent by chemical means in the sample solution. It is sometimes also possible to incorporate a membrane into the sensor, which shows selective transport or which contains a catalyst (such as an enzyme) enabling lower applied potentials and thus leading to improved selectivity.

The amperometric sensor has to be completed with counter and reference electrodes in order to carry the cell current and define the applied potential, respectively. In conventional voltammetry or amperometry, a three-electrode configuration is commonly used where two different electrodes fulfill these functions. In the design of amperometric sensors two-electrode systems are often used for simplicity. The counter electrode then serves as a reference as well. This requires a tolerance to a steady current over prolonged periods of time without a significant change in electrode potential. In either case, the current on the counter electrode causes the oxidation or reduction of a species that has to be considered when designing the sensor. The material consumed has to be incorporated into the probe on construction or provided as a refillable electrolyte solution. The amount available determines the lifetime of the sensor unless some other process (e.g., fouling of a membrane) has a more significant effect.

## Sensors for Dissolved Oxygen

The determination of dissolved oxygen in aqueous systems is of great importance in environmental and clinical applications. Prior to the introduction of oxygen sensors this analysis was mainly carried out with a chemical titration procedure according to Winkler. In this method, Mn(II) is oxidized to Mn(III) by analyte oxygen in a basic solution. This is followed by the oxidation of  $I^-$  to  $I_2$  by Mn(III) in acidic solution and the subsequent titration of the iodine produced with thiosulfate. The procedure is therefore very labor and time intensive and does not allow online or *in vivo* measurements. The use of a sensor for oxygen determination represents a significant improvement and has largely replaced the older chemical method.

The concentration of dissolved oxygen in solution that is in equilibrium with a gas mixture is determined by its partial pressure in the gas volume according to Henry's law:

$$p = k'c \quad [2]$$

where  $p$  is the partial pressure,  $k'$  a constant that is specific for oxygen and the solvent used, and  $c$  the concentration in the solution. The partial pressure is dependent on the barometric pressure. For clean air the volume fraction of oxygen is a constant (20.095%) and may be used to derive the partial pressure from the barometric reading. However, air in contact with water will take up moisture and this will fractionally lower the partial pressures of all constituents in air. For precise oxygen determinations

the partial pressure of water in air has to be considered and an appropriate correction for the partial pressure of oxygen also needs to be made.  $k'$  is dependent on temperature. The solubility of gases in water decreases with increasing temperature in a nonlinear fashion and is zero at the boiling point. A further dependence is found on the salt content of the solution. The solubility of oxygen decreases with increasing salt concentration. There is also a dependence on the pressure of the water body itself. The solubility of oxygen remains fairly constant, but the partial pressure increases with depth. This factor becomes important when determining dissolved oxygen in natural waters. Chemical methods like the Winkler titration method respond to the concentration, while amperometric oxygen sensors respond to partial pressure and therefore show this depth dependence. It is, however, possible to carry out a numerical correction based on thermodynamic principles for this pressure effect.

Oxygen can be reduced at a cathode according to the following reactions:

In basic solutions:

In acidic solutions:

The standard potentials,  $E^\circ$ , on platinum electrodes are +0.81 V at pH 7, +0.40 V at pH 14, and +1.23 V at pH 0. These standard potentials correspond to the potential where the rise in current is obtained in the current versus voltage plots. For basic solutions a plateau is obtained over several 100 mV before hydrogen evolution sets in at more negative potentials.

On a mercury electrode the reaction proceeds in two steps with distinct potentials:

A conventional polarograph with a dropping mercury electrode may indeed be employed for the determination of dissolved oxygen.

## Oxygen Sensing without Membranes

Currently, most amperometric sensors for dissolved oxygen contain a membrane to separate the working and counter electrodes from the sample solution. However, open cells had been used exclusively prior to the introduction of membrane based sensors. The electrolyte solution for these systems is the sample

solution and the electrodes are therefore susceptible to interferences such as spurious electrode reactions by redox active substances in the sample and electrode poisoning. Another problem is the ill-defined counter electrode reaction that leads to a poor control of the cell voltage. Despite these drawbacks, open cells are still used when membrane contamination would be a problem (such as in sewage treatment). Frequent automated mechanical cleaning of the electrodes may be employed in such cases to eliminate electrode poisoning.

### Oxygen Sensing with Membranes

The disadvantages of the membraneless systems were largely overcome in 1956 by Clark who placed both working and counter electrodes behind a gas-permeable membrane that holds an internal electrolyte solution in place. This concept has since been widely accepted and this type of oxygen sensor is frequently called a Clark electrode. Note that the term electrode is used even though the sensor comprises a complete electrochemical cell.

A schematic drawing of a typical Clark-type cell is given in Figure 3. The working electrode is located behind the membrane separated by only a thin layer of electrolyte solution in order to achieve a fast response. Gold or platinum electrodes are almost universally used because of the scarcity of interfering reactions on these metals. In principle, it is possible to reduce oxygen at these electrodes over a wide pH range since oxygen reduction is obtained for acidic as well as basic solutions, albeit according to two different mechanisms as given in reactions [I] and [II].

The counter electrode is commonly a silver anode, can be located at a distance from the membrane, and has to possess a relatively large surface area in order not to limit the current flow. It is necessary that the reaction products are obtained from a solid layer on the anode and do not enter the electrolyte solution as particles that may short-circuit the cell. The electrolyte solution is normally alkaline and the reference reaction is either:

or

A basic potassium chloride or bromide solution ( $\text{X}^- = \text{Cl}^-$  or  $\text{Br}^-$ ) is used as electrolyte solution. The depletion of the halide concentration in these cases over time will lead to the second reaction becoming the counter electrode process that will shift the cell potential to values  $\sim 120$  mV more positive.

**Figure 3** Schematic representation of the cross-section of a Clark electrode. 1, Au or Pt cathode; 2, Ag anode; 3, membrane; 4, electrolyte solution; 5, electrode body; 6, O-ring for fixing the membrane.

This may or may not shift the cell potential out of the plateau region for oxygen reduction, which would lead to a failure of the device because of hydrogen evolution. The basicity of the electrolyte solution tends to cause absorption of ambient carbon dioxide and the resulting lowering of the pH value may lead to hydrogen evolution and a failure of the device. This can be a problem for environments with high  $\text{CO}_2$  levels and may require frequent replacement of the electrolyte solution. Special Clark electrodes that use a  $\text{KHCO}_3$ -buffered electrolyte solution to prevent changes in pH value are available for critical cases. Silver is prone to sulfide poisoning, which may be a problem in environments containing high levels of sulfides.

### Membrane Materials

Different types of membrane materials such as polyethylene, silicon rubber, and poly(vinyl chloride) can be used. The sensitivity is higher and the response time of the sensor is shorter the thinner the membrane and the higher the permeability for oxygen. The permeability is a function of both solubility and diffusion rate of the gas in the polymer,

but is usually dominated by the latter. Silicone rubber has by far the highest permeability for oxygen, but in practice polyethylene or porous polytetrafluoroethylene (PTFE) of 10–20  $\mu\text{m}$  thickness is most often used, because these materials have high strength and can therefore be easily manufactured in thin sheets. For PTFE membranes the diffusion occurs through the pores that are not wetted due to the high hydrophobicity of the material. The membranes can usually be replaced by the user and are commonly held in place with an O-ring. It is important that on mounting the membranes are stretched flat across the electrode body without any creases as this would lead to irreproducible results.

### Interferences

The membrane material used imparts some degree of selectivity because the permeability varies for different gases. The diffusion rate and therefore the permeability is generally higher the smaller the molecule. On this principle, however, it is not possible to completely prevent gases other than oxygen from entering the electrolyte solution. Gases that have a reduction potential lower than that of oxygen on the precious metal cathode, such as  $\text{Cl}_2$ ,  $\text{NO}$ , and  $\text{CH}_2\text{O}$ , will be reduced and therefore will interfere. If these gases are only present at constant concentrations much lower than oxygen, this is not a serious problem, since it will result in a steady background current that can be electronically subtracted.  $\text{CO}_2$  interferes by lowering the pH value of the electrolyte solution as discussed above and  $\text{H}_2\text{S}$  and other sulfide gases tend to poison the silver anode. In severe cases it may be necessary to scrub interfering gases from the sample before measurements. Gases that cannot be reduced on the electrode, such as  $\text{NH}_3$ ,  $\text{CO}$ ,  $\text{CH}_4$ ,  $\text{N}_2$ ,  $\text{H}_2$ , and rare gases, do not interfere.

The cross-sensitivity to other gases has been employed to construct amperometric sensors for those species. Commonly used, for example, are sensors for dissolved chlorine (e.g., in swimming pools), which are very similar in construction to Clark electrodes for oxygen.

### Temperature Dependence

Amperometric oxygen sensors show a large dependence on temperature, an increase of current of  $\sim 2\% \text{ } ^\circ\text{C}^{-1}$  is observed. This is caused by the temperature dependence of the diffusion coefficient for oxygen in the membrane. A temperature sensitive element such as a thermistor is therefore often incorporated in the cell to allow electronic compensation for this source of error. It is obvious that

the temperature measuring component has to be located as close to the membrane as possible.

### Dynamic Range

Clark-type electrodes show a linear response over almost four orders of magnitude. The upper limit is determined by the saturation of the sample with dissolved oxygen ( $\sim 10 \text{ mg l}^{-1}$  in water at atmospheric pressure) while the lower limit is caused by the so-called residual current. This is due to impurities that can be reduced on the cathode, as well as trace oxygen present in the electrolyte solution or gassing out from the solid materials comprising the sensor body. A typical detection limit is  $0.05 \text{ mg l}^{-1}$  of dissolved oxygen.

### Sensitivity

The sensitivity of amperometric sensors can, in principle, be increased by making the working electrode surface larger. However, this may lead to an increased thickness of the diffusion layer that causes a reduction of the flux of the sensed species to the electrode and therefore a reduction in sensitivity. In practice, it is therefore often desirable to use microelectrodes. If the diffusion layer extends into the sample solution, increasing the stirring rate or the flow rate may lead to a reduction of the diffusion layer thickness and hence lead to an increased sensitivity as well as faster response times. Varying the thickness of a membrane may have a similar effect. The dependence of the sensitivity on flow rates may be a disadvantage and can again be overcome by using microsensors with diameters in the micrometer range. As an increase in temperature increases the diffusion coefficient this may be used to enhance sensitivity. However, the increase in current that comes with higher sensitivity also leads to a faster consumption of the counter electrode species and therefore to a reduced lifetime. A high sensitivity and therefore high rate of analyte consumption may also cause a depletion of the analyte species in the vicinity of the sensor leading to an erroneous low reading. This is, of course, particularly significant if small sample volumes are analyzed.

### Response Time

The response time of the sensor is given by the time required for establishment of equilibrium within the diffusion layer on changing the applied potential, or of more relevance, a change in the analyte concentration. This process is faster for thinner diffusion layers. In cases where the diffusion and the stagnant layers coincide, the response time can be controlled by stirring, flow rate, or rotation or other movement

of the sensor itself. If the diffusion layer is confined to a membrane it is the membrane thickness that determines the response time. The response time is then faster for thinner membranes. On the other hand, the diffusion layer for thin membranes might extend into the sample solution which again leads to a flow rate dependence.

The response time is usually expressed as the time required to reach 90% of the final change in current ( $t_{90}$ ). This is usually  $\sim 15\text{--}20$  s; however, it is necessary to wait for  $\sim 1$  min to obtain a stable reading. The response time of the electrode on switching on the cell voltage is, in principle, also determined by the time required for establishment of the diffusion layer. However, in practice, other factors, such as the reduction of an oxide layer on the electrode surface, the desorption of impurities from the electrode, and the increase of the pH value in the electrolyte solution layer immediately adhering to the electrode surface due to the production of hydroxide ions by the electrode reaction, further delay the attainment of the equilibrium current. The electrodes are therefore usually conditioned (polarized) by permanently applying the cell potential between measurements.

### Calibration

A calibration can be carried out by saturating water with air, pure oxygen, or known gas mixtures. The latter can be produced with flow meters or are commercially available in compressed form. It is also possible to use water saturated with air and mix it in known ratios with oxygen-free water. Alternatively, the oxygen content of different solutions may be established with a different procedure such as the chemical determination with the Winkler method. Once the linearity of the response has been established, it is, however, not always necessary to acquire a complete calibration curve. A two-point calibration check is usually adequate. The procedure is then similar to the calibration of pH electrodes. A solution of zero oxygen content and a solution with a known concentration are used to set the zero point and sensitivity of the electrode, respectively (intercept and slope of the calibration line). Solutions free of oxygen may be obtained by boiling, bubbling through an inert gas ( $\text{N}_2$ , Ar), or chemical decomposition with, e.g., 2% sodium sulfite. The solution used to adjust the sensitivity should show high oxygen content. The calibration for sensitivity may be carried out in air rather than in aqueous solution for simplicity. However, for precise measurements it has to be considered that the partial pressure of oxygen in air depends on the humidity of the air. To overcome this dependency it should be ensured that the air used for

calibration is saturated with moisture by holding the electrode in this process closely over the surface of clean water. The partial pressure of water for the given temperature and the resulting partial pressure of oxygen can be obtained from tables.

### Applications

The Clark electrode was originally conceived for use in online *in vivo* determination in blood streams during surgery. Noninvasive, even bedside, monitoring of blood oxygen content is now possible with the simple and elegant optical method of pulse oximetry (but note that it is oxygen saturation which is measured, not partial pressure as with the Clark electrode) but other applications remain highly important. Microelectrodes that allow high spatial resolution (e.g., measurements in single cells) are in use. The measurement of dissolved oxygen in blood samples is routinely carried out with Clark electrodes in clinical analysis as one of the standard parameters. The Clark electrode is also widely used in the determination of dissolved oxygen in natural waters (lakes, rivers, seawater) for environmental studies. In order to carry out measurements at large depths in natural waters at high pressure, special versions of the Clark electrode with pressure compensation are available, as are small sensors for use in spatial profiling of the sediment layer of water bodies. The determination of oxygen in fresh water supplies and boiler feed water is also often carried out. In the treatment of sewage, the continuous monitoring of oxygen content is highly important. The probes are widely used in the determination of biological and chemical oxygen demand of water. Clark electrodes have also been employed as the active sensing element in enzymatic sensors where oxygen is produced or consumed as part of the reaction with the analyte. Microscale Clark-type sensors have been created in silicon employing microlithographic manufacturing techniques.

### Sensors for Atmospheric Oxygen

The Clark electrodes described above are not suitable for oxygen determination in dry gaseous samples such as air because the thin layer of electrolyte solution contained behind the membrane is prone to rapid drying. A different arrangement is therefore used for such applications. Amperometric gas sensors for oxygen (and sensors for other electroactive species in the vapor phase) usually consist of a porous PTFE membrane that bears a precious metal electrode deposited, also in porous form, directly on the backside. This keeps the diffusion length short while

allowing the inclusion of a larger volume of electrolyte solution (typically ~5–10 ml) and alleviating problems due to evaporation. An artificial additional diffusion barrier, such as a porous cover plate, is often needed in order to obtain a linear concentration dependence and to eliminate sensitivity to drafts in the sample gas.

If the reference electrode system is chosen such that the cell potential is sufficient to cause the sensing electrode reaction to proceed, the sensor acts as a galvanic cell and it is not necessary to apply an external voltage. It is possible to use, for example, Pb as anode with the following reference reaction:

The standard potential for these electrodes is  $-0.58\text{ V}$  and therefore the cell reaction occurs spontaneously. These cells are sometimes referred to as ‘Mackereth sensors’. Such galvanic sensors are also often termed ‘fuel cell sensors’ and it is possible to measure either the resulting current or the cell voltage. In the former case, the term amperometric sensor in its widest definition is still correct, although the cell is fundamentally different from the usual Faradaic amperometric systems. Note that for the determination of atmospheric oxygen an alternative has become available in recent years in the form of optical sensors based on fluorescence. These sensors are very robust as they do not contain electrodes or a liquid phase and show very fast response times.

One further important application of oxygen sensing is the direct analysis of automobile exhausts. For this purpose an amperometric sensor based on a solid

electrolyte phase can be used. Yttrium-stabilized zirconia ( $\text{ZrO}_2\text{--Y}_2\text{O}_3$ ) forms an electrolyte that is conductive for  $\text{O}^{2-}$  ions at temperatures above  $400^\circ\text{C}$ . Both the reduction and oxidation reactions can be catalyzed by porous platinum electrodes deposited on the zirconia:

If two such electrodes are separated by a thin layer of only zirconia, the application of a potential will lead to the pumping of oxygen from the cathode to the anode. This device can be used as an amperometric sensor for oxygen if a diffusion barrier restricts the flux of oxygen to the cathode. Note that similar devices are also often used as potentiometric sensors according to the Nernst equation (i.e., the lambda-probe in cars with catalytic converters). In this case one side of the cell has to act as a reference, e.g., by using ambient air.

## Introduction

The most attractive feature of calorimetric sensors is the fact that they are based on an almost universal detection principle that is insensitive to the optical or electrochemical properties of the sample. The usefulness of calorimetry as an analytical tool in biology

has long been recognized, but it was not until immobilized enzymes had been introduced in bioanalysis that the development of simpler calorimetric sensors took place in the mid-1970s. The conventional (micro)calorimeters available before this time, although adequate for more precise analyses, were less suitable for routine analyses because of their high cost and time-consuming operation. Immobilized enzyme technology made it possible to construct simpler analytical devices by applying the enzymes in reactors or in layers close to the temperature transducer. Similar to the enzyme electrodes, calorimetric enzyme sensors found applications in many bioanalytical fields, such as clinical chemistry, environmental control, and bioprocess analysis. Enzymatic

reactions are usually associated with rather high enthalpy changes, in the range of 20–100 kJ mol<sup>−1</sup>, which is often sufficient for designing assays based on only one enzymatic step. The combined heat production from sequential or cycling enzymatic reactions may also be utilized to increase the overall sensitivity. In addition, it is equally simple to combine calorimetric sensors with immobilized cells or enzymes or cells in flow streams.

Owing to their outstanding versatility in bioanalysis, this treatment of calorimetric/enthalpimetric sensors will focus on thermal bioanalyzers or biosensor systems. The most sensitive and practically useful calorimetric sensor arrangements involve continuous flow operation (viz., flow injection analysis), although several attempts have been made to create calorimetric enzyme probes simply by coating the temperature transducer with an enzyme layer. However, these measurements, which are carried out differentially using an inactive reference probe, suffer from poor sensitivity. Recent designs of miniaturized flow calorimetric sensors show that most of the sensitivity can be preserved concurrent with increased analysis speed and decreased equipment complexity. Such sensors may find use in portable monitoring, for instance, the home monitoring of glucose in diabetes care.

## Principles

The total heat evolved in a reaction is proportional to the molar enthalpy change:

$$Q = -n_p \Delta H \quad [1]$$

where  $Q$  is the total heat,  $n_p$  the moles product, and  $\Delta H$  the molar enthalpy change.

The total heat is also dependent on the heat capacity,  $C_s$ , of the system including the solvent:

$$Q = C_s \Delta T \quad [2]$$

Consequently, the measured temperature change,  $\Delta T$ , is dependent on the molar enthalpy change and the heat capacity:

$$\Delta T = -\frac{\Delta H n_p}{C_s} \quad [3]$$

Table 1 lists the molar enthalpy changes of some common enzyme-catalyzed reactions. Because enthalpimetric measurements are based on the sum of all enthalpy changes in the reaction mixture, it is common to coimmobilize oxidases with catalase, which approximately doubles the sensitivity at the same time as the oxygen consumption is reduced and

**Table 1** Molar enthalpy changes for some enzyme-catalyzed reactions

Enzyme	Substrate	$-\Delta H$ (kJ mol <sup>−1</sup> )
Catalase	Hydrogen peroxide	100
Cholesterol oxidase	Cholesterol	53
Glucose oxidase	Glucose	80
Hexokinase	Glucose	28 (75) <sup>a</sup>
Lactate dehydrogenase	Sodium pyruvate	62
NADH dehydrogenase	NADH	225
$\beta$ -Lactamase	Penicillin G	67 (115) <sup>a</sup>
Trypsin	Benzoyl-L-arginineamide	29
Urease	Urea (phosphate buffer, pH 7.5)	61
Uricase	Urate	49

<sup>a</sup>The  $\Delta H$  values in parentheses were obtained in TRIS buffer (protonation enthalpy  $-47.5$  kJ mol<sup>−1</sup>).

Reprinted from Blum LJ and Coulet PR (eds.) (1991) *Biosensor Principles and Applications*. New York: Dekker, by courtesy of Marcel Dekker, Inc.

deleterious effects of hydrogen peroxide are minimized. The high protonation enthalpy of buffer ions, such as tris(hydroxymethyl)aminomethane (TRIS), can be utilized to increase the total enthalpy change of proton-producing reactions (Table 1). Extreme increases in detection limit (to  $<10$  nmol l<sup>−1</sup>) can be obtained in substrate or coenzyme recycling enzyme systems, where the net enthalpy change of each turn of the cycle adds to the overall enthalpy change. An enthalpy change of 100 kJ mol<sup>−1</sup> is sufficient for substrate determinations with a detection limit better than 0.005 mmol l<sup>−1</sup>.

In enthalpimetric flow injection analysis, the sample pulses employed are too small to give a thermal steady state, but result in a temperature peak proportional to the enthalpy change and thereby to the substrate concentration. The peak height, the area under the peak, and the ascending slope of the peak are all linearly related to the substrate concentration. Sample introduction of a sufficient duration (several minutes) leads to a thermal steady state resulting in a constant temperature deviation, which is also proportional to the substrate concentration.

An inherent disadvantage of calorimetry is the lack of specificity: all enthalpy changes in the reaction mixture contribute to the measurement. It is therefore important to avoid nonspecific enthalpy changes from dilution or solvation effects. However, in the majority of cases this is not a serious problem. Differential measurement using a reference column containing an inactive filling is an efficient way of coping with nonspecific and matrix effects.

## Sensor Design

Thermistors, metal oxide resistors with a very high negative temperature coefficient of resistance, are normally used as temperature transducers in enthalpimetric sensors. They can be obtained in many different configurations, sizes (down to 0.1–0.3 mm beads or deposited as thin films), and resistance values. For narrow temperature ranges, the resistance–temperature relationship can be approximated by the following equation:

$$R_T = R_{T_0} e^{\beta(1/T - 1/T_0)} \quad [4]$$

where  $R_T$  and  $R_{T_0}$  are the zero-power resistances at the absolute temperatures  $T$  and  $T_0$ , respectively.  $\beta$  is a material constant that ranges between 4000 and

5000 K for most thermistor materials. This results in a temperature coefficient of resistance between  $-3\% ^\circ\text{C}^{-1}$  and  $-5.7\% ^\circ\text{C}^{-1}$ .

Other temperature transducers employed in calorimetric analyzers include Peltier elements, Darlington transistors, and thermopiles. Thermopiles can be made in very small dimensions using current semiconductor technology and are less flow-sensitive than thermistors, though the latter provide higher temperature resolution.

An example of the instrumentation used in the author's laboratory is shown in Figure 1. The calorimeter part of this two-channel instrument consists of an outer aluminum cylinder ( $80 \times 250$  mm) thermostatted to  $25^\circ\text{C}$ ,  $30^\circ\text{C}$ , or  $37^\circ\text{C}$  and a second inner aluminum cylinder with two column ports and a pocket for a reference thermistor. The solution to be

**Figure 1** Cross-section of the calorimeter of an enzyme thermistor with an aluminum constant temperature jacket. The two identical column ports (one temperature probe with a column is shown) can be used independently or one of the ports can be used for a reference channel. The column attachment is illustrated on the left. (Reprinted with permission from Danielsson B (1990) *Journal of Biotechnology* 15: 187–200; © Elsevier.)

analyzed is introduced via a thin-walled acid-proof steel tubing (typically 0.8 mm ID). Two-thirds of the tubing's length is in close contact with the thermostatted jacket, while the last third is in close contact with the inner cylinder, which acts as a heat sink. This arrangement results in exceedingly small temperature variations (short term) in the column. The column is inserted by a long Delrin tube containing the temperature sensor. The DC-type Wheatstone bridge is equipped with a chopper-stabilized low-drift operational amplifier and has maximum sensitivity of 100 mV per 0.001 °C. Temperatures in the range of 0.01–0.05 °C are commonly measured for enzymatic reactions.

## Performance

The equipment shown in **Figure 1** is operated with a continuous flow of a buffer (0.5–5 ml min<sup>−1</sup>) using sample volumes of 0.01–0.5 ml in flow injection mode. Small sample volumes (<25 µl) may be injected undiluted, while larger samples should be diluted at least 5- to 10-fold in buffer so as to avoid nonspecific thermal effects due to mixing.

Columns up to 1 ml (at 7 mm ID) can be used. The enzyme support should have good binding capacity and good mechanical, chemical, as well as microbial stability and involve relatively simple coupling procedures. These demands are satisfied by controlled pore glass (CPG), which has been the most common enzyme support in our investigations (80–120 mesh, pore size 500–2000 Å). Cells can be immobilized by entrapment in alginate or gelatin beads. Where possible a large excess of enzyme is applied; 100 units or

more. The major factor limiting column life is mechanical obstruction. If the solutions and samples are filtered through a 1–5 µm filter and assuming microbial growth is prevented, good operational stability and reproducibility for a large series of samples (thousands) can be achieved. The column lifetime can be several months of continuous use.

**Table 2** shows a number of substances for which enthalpimetric assays have been carried out. The linear ranges given may not in all cases represent what is ultimately achievable under optimal conditions. The data are from various studies from different laboratories and with different equipment. For an enthalpy change of ~200 kJ mol<sup>−1</sup>, such as for glucose oxidase combined with catalase, it is possible to come down to a limit of detection of 1 µmol l<sup>−1</sup> with the equipment described above. At the same time, the linear range may extend to several hundred millimoles per liter with a highly active column in reactions that are not limited by the availability of coreactants. The use of recycling techniques may result in several thousand times greater sensitivity. The precision of the measurement can be as good as 0.5% (relative standard deviation).

## Major Applications

### Metabolite Assays

A large number of enthalpimetric assays based on immobilized enzyme reactors have been proposed with potential interest to biotechnology, clinical chemistry, and food analysis. Several of these have been applied in bioprocess monitoring and recently bedside monitoring of glucose and urea have been

**Table 2** Linear concentration ranges of substances measured with enthalpimetric sensors using immobilized enzymes

Analyte	Enzyme(s) used	Concentration range (mmol l <sup>−1</sup> )
Ascorbic acid	Ascorbate oxidase	0.01–0.6
ATP (or ADP)	Pyruvate kinase + hexokinase	10 nmol l <sup>−1</sup> <sup>a</sup>
Cellobiose	β-Glucosidase + glucose oxidase/catalase	0.05–5
Cephalosporins	Cephalosporinase (β-lactamase)	0.005–10
Creatinine	Creatinine iminohydrolase	0.01–10
Ethanol	Alcohol oxidase	0.005–1
Glucose	Hexokinase	0.5–25
Glucose	Glucose oxidase/catalase	0.001–0.8 (75) <sup>b</sup>
L-Lactate	Lactate-2-mono-oxygenase	0.005–2
L-Lactate	Lactate oxidase/catalase	0.002–1
L-Lactate (or pyruvate)	Lactate oxidase/catalase + lactate dehydrogenase	10 nmol l <sup>−1</sup> <sup>a</sup>
Oxalate	Oxalate oxidase	0.005–0.5
Penicillin	β-Lactamase	0.005–200
Sucrose	Invertase	0.05–100
Urea	Urease	0.005–200

<sup>a</sup>With substrate recycling.

<sup>b</sup>With benzoquinone as electron acceptor.

demonstrated. To illustrate the possibilities and limitations of the technique a few assays will be discussed in some detail. The concentration ranges given have in general been obtained with 0.5 ml sample volume at a flow rate of  $1 \text{ ml min}^{-1}$ . The sensitivity can be adapted to higher concentrations by dilution and use of smaller sample volume.

**Alcohols** Lower alcohols have been measured with alcohol oxidase (EC 1.1.3.13) from *Candida boidinii* or *Pichia pastoris*. The latter is available with a higher specific activity and has a somewhat different substrate specificity. Coimmobilization with catalase increases the stability of the enzyme column to several months with an operating range of  $0.005\text{--}1 \text{ mmol l}^{-1}$  (0.5 ml samples) using  $0.1 \text{ mol l}^{-1}$  sodium phosphate, pH 7.0, as the buffer. This assay is useful for the determination of ethanol in samples from beverages, blood, and for monitoring fermentation.

**Cellobiose** Since the heat produced by the hydrolysis of cellobiose with  $\beta$ -glucosidase is too low to give acceptable sensitivity, a procedure has been designed in which the glucose formed in a precolumn containing  $\beta$ -glucosidase is measured with a glucose oxidase/catalase loaded enzyme thermistor. The operating range is  $\sim 0.05\text{--}5 \text{ mmol l}^{-1}$ .

**Cholesterol and cholesterol esters** Cholesterol has been determined in  $0.16 \text{ mol l}^{-1}$  phosphate buffer, pH 6.5, containing 12% (v/v) ethanol and 8% (v/v) Triton X-100 using cholesterol oxidase (EC 1.1.3.6) from *Nocardia erythropolis*. Cholesterol esters were measured after treating the samples with cholesterol esterase (EC 3.1.1.13). The measuring range is adequate for clinical use).

**Creatinine** The microbial enzyme creatinine deiminase (EC 3.5.4.21) works well in the enzyme thermistor giving a linear range from 0.01 to at least  $10 \text{ mmol l}^{-1}$ . This could be a very powerful assay for clinical use since it requires only one enzyme and is independent of endogenous ammonia. Unfortunately, the determination of creatinine in human serum requires a higher order of magnitude increase in sensitivity than is available with the present instrumentation.

**Glucose** Very useful assays for various bioanalytical applications have been developed based on calorimetry, usually with glucose oxidase coimmobilized with catalase. The addition of catalase more than doubles the total enthalpy change, eliminates the deleterious effects of the hydrogen peroxide formed in the glucose oxidase reaction, and restores half of

the oxygen consumed by this reaction. This procedure provides high sensitivity and specificity and it has no cofactor requirement. The enzyme columns are very stable. The most serious disadvantage is that the useful concentration range is limited to  $<0.7\text{--}1.0 \text{ mmol l}^{-1}$  by the supply of oxygen, which is soluble only to a small extent in water,  $\sim 0.25 \text{ mmol l}^{-1}$  at  $25^\circ\text{C}$ . A more soluble electron acceptor than oxygen, such as benzoquinone, increases the useful working range considerably to at least  $75 \text{ mmol l}^{-1}$ . Alternatively, the enzyme hexokinase can be used. The requirement for the cofactor adenosine 5'-triphosphate (ATP) is a drawback; however, a linear range of up to  $25 \text{ mmol l}^{-1}$  can be obtained.

**L-Lactate** L-Lactate can be determined with two different enzyme systems: the lactate-2-mono-oxygenase (EC 1.13.12.4) from *Mycobacterium smegmatis* providing a linear range of  $0.005\text{--}2 \text{ mmol l}^{-1}$  in  $0.2 \text{ mol l}^{-1}$  sodium phosphate buffer, pH 7.0, or the lactate oxidase from *Pediococcus pseudomonas* (EC 1.1.3.2) together with catalase giving a linear range of  $0.002\text{--}1 \text{ mmol l}^{-1}$  in  $0.1 \text{ mol l}^{-1}$  phosphate buffer, pH 7.0.

**Oxalate** Oxalate can be determined with oxalate oxidase (EC 1.2.3.4) from barley seedlings. The linear concentration range is  $0.005\text{--}0.5 \text{ mmol l}^{-1}$  in  $0.1 \text{ mol l}^{-1}$  sodium citrate buffer, pH 3.5, containing  $2 \text{ mmol l}^{-1}$  ethylenediaminetetraacetic acid (EDTA) and  $0.8 \text{ mmol l}^{-1}$  8-quinolinol. This assay has been found suitable for the determination of oxalate in urine, beverages, and food samples. Urine samples are preferably diluted 10-fold and passed through a  $\text{C}_{18}$ -cartridge to remove interfering substances.

**Penicillin G and V** Very useful procedures for the assay of  $\beta$ -lactams, such as penicillin G and V, have been designed using  $\beta$ -lactamases, such as penicillinase type I from *Bacillus cereus* (EC 3.5.2.6). The useful linear range is  $\sim 0.005\text{--}200 \text{ mmol l}^{-1}$ . Several industrial applications have been developed using both discrete samples and continuous monitoring on pilot-plant and production-scale fermentors. Alternatively, the penicillin amidase (EC 3.5.1.11) has been used which shows better specificity in fermentation broths. The sensitivity is, however, lower although sufficient for many purposes. In both cases, the enzyme columns are very stable and can be used for several months or for thousands of samples.

**Sucrose** In contrast to most other disaccharide splitting enzymes, invertase (EC 3.2.1.26) produces enough heat to allow direct determinations of sucrose in the range of  $0.05\text{--}100 \text{ mmol l}^{-1}$ , even in

the presence of glucose. Invertase columns are very stable and useful in food and bioprocess analysis.

**Triglycerides** Practical routine methods for the determination of the main blood lipid classes, cholesterol and cholesterol esters, phospholipids, and triglycerides have been proposed. Triglycerides have been determined with lipoprotein lipase (EC 3.1.1.34) immobilized on CPG with a pore size of 200 nm. The assay buffer was  $0.1 \text{ mol l}^{-1}$  TRIS buffer, pH 8.0, containing 0.5% Triton X-100. The linear response was  $0.05\text{--}10 \text{ mmol l}^{-1}$  for tributyrin and  $0.1\text{--}5 \text{ mmol l}^{-1}$  for triolein.

**Urea** Another common metabolite that has attracted a great deal of interest is biosensor analysis of urea. Urease, which gives a linear range of at least  $0.01\text{--}200 \text{ mmol l}^{-1}$ , offers a clinically useful assay that is independent of the ammonium concentration in the sample, the same as with creatinine. Urease is very sensitive to inhibition by heavy metals. This fact has even been exploited in the design of a reversible procedure for heavy metal determination. Addition of  $1 \text{ mmol l}^{-1}$  EDTA and  $1 \text{ mmol l}^{-1}$  reduced glutathione to the buffer protects the urease leading to a very stable enzyme column.

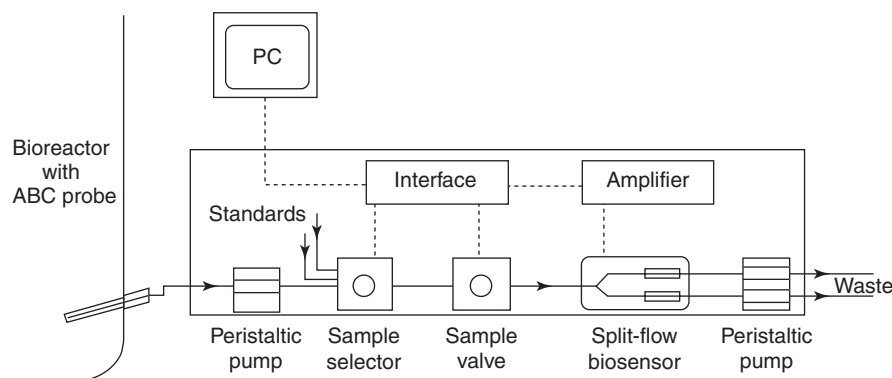

Other metabolites that have been measured with calorimetric sensors include ascorbic acid, ATP/ADP (adenosine 5'-diphosphate), cephalosporins, galactose, hydrogen peroxide, lactose, malate, phospholipids, uric acid, xanthine, and hypoxanthine.

### Process Control

Monitoring and control of (bio)processes was identified early on as a suitable application field for biosensors, but only recently have really practical

systems been introduced. Owing to their outstanding versatility, calorimetric sensors are particularly suitable for this purpose. Since a biosensor cannot usually be placed directly in the sample, for instance, inside a fermentor that needs to be sterilized before use, a sample stream has to be drawn from the process solution. This must be done under strictly sterile conditions to avoid microbial contamination of the bioprocess and to remove cells from the sample solution in order to prevent cells from attaching inside the apparatus and to stop changes in the composition of the sample during its transport. Preferably this is done by filtration or dialysis. There has been a lack of suitable devices for sample filtration, but recently various sterilizable, small cross-flow (tangential flow) filtration units have been introduced that work well, at least with larger fermentors where the spent sample stream can be discarded. A filtration probe that consists of a large (8 mm diameter)  $0.2 \mu\text{m}$  hollow-fiber filter in a holder that is inserted into the fermentor through a standard port and that can be steam sterilized *in situ* has been found to perform very well with larger as well as with smaller fermentors.

Such a filtration probe has been tested with very good results in a number of analyses with a special enzyme thermistor version designed for use in industrial environments. **Figure 2** is a schematic illustration of an enzyme thermistor arranged for process monitoring by repeated flow injection analysis. The interval between sample injections is chosen with respect to how fast the analyte concentration changes. A typical figure is four to five sample injections per hour. The injection valve and a sample selector valve for selection of different samples or calibration solutions and the pumps are controlled with a personal computer with a 386 processor, which also

**Figure 2** Setup for bioprocess monitoring. A continuous sample stream ( $1\text{--}3 \text{ ml min}^{-1}$ ) is drawn from the bioreactor using a filtration probe (ABC probe) and a peristaltic pump. The signal from the split-flow enzyme thermistor is recorded with a computer via a 12-bit AD-converter and an interface that also connects with the valves and pumps. (Reprinted with permission from Rank M, Gram J, and Danielsson B (1993) Industrial on-line monitoring of penicillin V, glucose and ethanol using a split-flow modified thermal biosensor. *Analytica Chimica Acta* 281: 521–526; © Elsevier.)

calculates the analyte concentration from the enzyme thermistor signal and stores and displays the data. The equipment is placed close to the fermentor in a climatized cabinet flushed with cool, dry air. In order to minimize nonspecific heat signals, a split-flow enzyme thermistor equipped with an inactive reference column is generally used. Measurements of various metabolites, including glucose, lactate, ethanol, glycerol, acetaldehyde, and penicillin, have been very successful on fermentors ranging in size from 0.5 to 160 m<sup>3</sup>. Fermentations lasting for 2 weeks can usually be followed without change of enzyme column.

### Miniaturized Calorimetric Sensors

Recently, several laboratories have started investigations on miniaturized calorimetric sensors. One type of device involves scaled-down versions of the more conventional flow calorimeter designs, and another is based on constructions made by micromachining in materials such as silicon, quartz, and glass. These approaches should lead to rapid, versatile, and inexpensive enthalpimetric analyses requiring very small samples and minimal reagent/enzyme consumption. Several sensors have been constructed primarily for glucose measurements directed toward diabetes care. One thermal biosensor probe, for instance, was designed as an integrated-circuit biocalorimetric sensor with total dimensions of only 1 × 1 × 0.3 mm with Darlington transistors as temperature-sensitive elements. Another design is a small thermoelectric glucose sensor that employs a thin-film thermopile to measure the evolved heat. This device was reported to be sufficiently less affected by external thermal effects than calorimetric sensors based on thermistors that it could be operated without environmental temperature control. Work is in progress in the author's laboratory to construct miniaturized biothermal flow injection systems suitable for portable monitoring. Instruments with 0.1–0.2 mm (ID) flow channels and a flow rate of 25–100 µl min<sup>-1</sup> with sample volumes of 1–10 µl are presently being evaluated with emphasis on whole blood determination of glucose. **Figure 3** shows one version of a miniature calorimeter.

Operation with whole blood samples puts special demands on the enzyme column. The investigations have followed two main routes, the use of superporous agarose beads with pores large enough for cells to pass through and the use of spherical, uniform beads large enough to let the cells pass unobstructed outside the beads. Both approaches have led to acceptable results; for instance, columns that can be used with at least 100 blood samples with satisfying precision. An example of a calibration graph for a

**Figure 3** Cross-section of a miniaturized calorimetric immobilized enzyme sensor equipped with a 1.5 × 15 mm column.

**Figure 4** Calibration graph for a calorimetric device of the type shown in **Figure 3** with a glucose oxidase/catalase column. The sample volume was 20 µl. Open squares are for aqueous glucose standards and closed squares are for 10-fold diluted blood samples spiked with glucose.

superporous agarose column with glucose oxidase and catalase used in a device of the type depicted in **Figure 3** is shown in **Figure 4**.

### Other Applications

The outstanding versatility of calorimetric sensors makes them useful in many other modes of operation than those described above. Some of these are briefly discussed below.

#### Environmental Control

The calorimetric detection principle has been exploited mainly in two different ways in environmental analysis. The first measures the heat of conversion of a pollutant by a cell metabolic route or a specific enzyme directly.

The second alternative, which is much more sensitive, measures the inhibitory effect of a pollutant on

an enzyme or on the metabolism of suitable cells. To detect an environmental pollutant by quantifying its effect on a biological system is ideal. The highly sensitive determination of heavy metals ( $\text{Hg}^{2+}$ ,  $\text{Cu}^{2+}$ , and  $\text{Ag}^+$ ) based on the inhibition of urease has already been mentioned. The detection limit is comparable to that of atomic absorption spectrometry or stripping voltammetry ( $\text{ng g}^{-1}$  levels) and the measurement involves comparatively simple equipment and procedures. The assay is carried out on an aqueous solution and does not create any hazardous wastes.

Another example is the determination of cholinesterase inhibitors (pesticides) using acetylcholine or butyrylcholine as substrate. Since the inhibition of the enzyme in this case is irreversible, it is convenient to use a reversible enzyme immobilization technique that allows for simple replacement of spent enzyme. This can be accomplished by reversibly binding the cholinesterase to a concanavalin A-agarose column. Many enzymes require metal ions in their active sites for catalytic activity. The metal ion can be removed using strong chelating agents resulting in an inactive apoenzyme that can be reactivated upon exposure to a sample containing the appropriate metal ion.

Similarly, the use of immobilized cell columns in calorimetric studies of metabolic effectors has great potential due to its general applicability. The metabolic heat is very likely to be affected by the presence of a metabolic poison, such as an environmental pollutant, or substances with an activating effect, such as vitamins. A wide variety of cell immobilization techniques are available, including entrapment with alginate in  $\text{Ca}^{2+}$  solution and entrapment in gelatin or agarose beads. It is important to maintain a sterile environment and to make the beads sufficiently small, at least  $<1\text{--}2\text{ mm}$ , to provide a short response time. Immobilized whole cells may offer several advantages over pure enzyme systems in metabolite assays especially where the pure enzyme is unstable or difficult to purify. This may be the case with reactions involving sequential multienzyme systems. Furthermore, cells provide built-in systems for coenzyme regeneration.

#### **Thermometric Enzyme-linked Immunosorbent Assay**

Rapid, sensitive determination of larger molecules, such as hormones and antibodies present, for instance, in fermentation broth, can be accomplished by an automated, flow-through thermometric enzyme-linked immunosorbent assay (TELISA), which is a competitive assay. The unlabeled antigen in the sample (or standard) is mixed with a fixed amount of

enzyme-labeled antigen and the mixture is then applied to the immunosorbent column mounted in the enzyme thermistor apparatus. The more unlabeled antigen in the sample, the less enzyme-labeled antigen will be bound to the column. The amount of enzyme (e.g., peroxidase or catalase) bound to the column is determined by injecting a pulse of substrate in excess. Finally, bound antigen is removed from the immunosorbent by washing with  $0.2\text{ mol l}^{-1}$  glycine-hydrochloric acid, pH 2.2, thereby regenerating the column for the next assay. One assay cycle is completed in 10–15 min. This method is very suitable for monitoring fermentations or when rapid results are desired for a limited number of samples. The sensitivity can be increased with use of recycling enzyme systems.

#### **Determination of Soluble Enzymes**

The enzyme thermistor can be used for the determination of the activity of soluble enzymes, by modifying the flow system and using an empty or inactive column, preferably made of polytetrafluoroethene, as a reaction chamber. The sample solution and substrate solution are passed through heat exchangers and thoroughly mixed. The mixture is then passed through a short heat exchanger to eliminate mixing and solvation heats. Enzyme activities down to  $0.01\text{ U ml}^{-1}$  can thus be determined. The technique is general and can be used with both sample pulses and with continuous sample introduction. It should be of particular interest for monitoring enzyme purification processes.

#### **Measurements on Cell Suspensions**

In a similar manner, the total metabolic heat generated by cells can be registered by mixing a flow stream containing the cells with a substrate stream or simply by letting a flow with cells, for instance, from a fermentor, pass through an empty enzyme thermistor column. This technique should be useful in studies of metabolic, effectors, and in toxicological studies and as a general method of following the overall metabolic state of a fermentation. The heat or the temperature level recorded represents the total metabolism of the microorganisms, and changes in the metabolism are directly detectable as changes in the temperature level.

#### **Measurements in Organic Solvents**

Enthalpimetric measurements in organic solvents should be up to three times more sensitive than in water because organic solvents have a lower heat capacity than water. This and the fact that enzymes can be active in organic solvents, although often

with changed specificity – or even reversed direction of the reaction – make it interesting to directly measure reactants in processes which are carried out in organic solvents. Furthermore, it would be of interest to develop assays in organic solvents for substrates with poor solubility in aqueous solutions. As an example, triglycerides can be determined directly in cyclohexane. Since the calorimetric measuring principle is as useful with endothermic reactions as with exothermic ones, it has been demonstrated that the enzyme thermistor can follow synthetic as well as hydrolytic reactions catalyzed by  $\alpha$ -chymotrypsin.

### Introduction

The concept of controlling the molecular architecture at the electrode/electrolyte interface was not known until ~30 years ago. Electrodes that can be prepared by deliberately immobilizing selected chemicals to display the desired electrochemical and other properties of the immobilized species are called chemically modified electrodes (CMEs). Since the emergence of CMEs, the field of electrochemistry has moved from traditional studies confined to inert electrode materials (such as bare C, Au, Hg, and Pt) at the interface.

With respect to enhanced sensitivity and selectivity in electroanalysis, the study of CMEs has been the most popular research area with studies ongoing in many electrochemistry laboratories. There is now a large body of research articles published in this field. This article outlines the latest achievements in CMEs, emphasizing applications in analytical chemistry. Based on the progress of modification, this article is

divided into four parts: (1) self-assembled monolayers (SAMs) on gold electrode and three-dimensional (3D) assembly; (2) mono- and multilayer assemblies on carbon electrode; (3) polymer film electrode; and (4) nanoparticle modified electrode.

### SAMs on Gold Electrode and 3D Assembly

The earliest molecular monolayer was made by sorption and covalent bonding of chemicals to electrode surfaces; however, limitations exist in the ability to control the structural and dynamic aspects of the immediate microscopic environment of the immobilized chemicals. SAMs that form spontaneously at solid/liquid interfaces have attracted much attention lately as it provides a unique technique for controlling the properties of solid surfaces. SAMs on electrodes give the platform needed for probing the relationship between the microstructure on the electrode surface and macroscopic electrochemical responses, which reach the top level of the molecular monolayer CMEs.

The progress made with respect to sensing interfaces is mainly due to the discovery and development of SAMs of sulfuric compounds on gold and other

conductive solid surfaces. As a typical example, alkanethiols chemisorb on gold surface forming a gold–thiol bond to produce a densely packed, highly ordered monolayer into two dimensions (2D). The strength of the head group–substrate interactions, the lateral interactions, and the density of packing result in sufficient stability, and the monolayer is robust enough to endure prolonged electrochemical measurement. The preparation of SAMs is quite easy and simple.

The idea of molecular defects or ‘gates’ within a blocking SAM was introduced for sensor applications while preparing SAMs wherein the density and the size of the ‘gates’ can be controlled. The species present in the electrolyte solution can respond selectively by the mixed SAMs prepared by a long chain alkanethiol and a short thiol to form phase-separated domains. Here, the domains with short thiols perform the role of ‘gates’ for the selective response of the species studied. The dendrimer has been used as molecular ‘gate’ to control the electrochemical behavior of the redox species present in the electrolyte when co-assembled with long chain alkanethiols. The Langmuir Blodgett (LB) technique has also been used to prepare such molecular ‘gates’ for the species studied with the deposition of long chain alkanethiol. The density and the size of the species can be controlled rationally and thus signals appear that are related to the isolated species from molecular ‘gates’. The introduction of the molecular ‘gates’ into SAMs provide an avenue for the in-depth study of analytical applications.

Molecular imprinting suggests a general method to tailor specific recognition sites in polymers or

inorganic materials, which has been recently introduced in SAMs to form a sensing interface. The reduced dimensionality at 2D monolayers would facilitate the association of the guest molecules to the imprinted sites, resulting in a fast response of the interface. The imprinted molecular recognition sites are formed by adsorption of the sites in alkanethiols on gold. However, the electrochemical behavior in such a case is not stable. The influence of the stability of the imprinted sites caused by the lateral diffusion of alkanethiols can be overcome by the co-adsorption of two types of molecules: the ‘template’ molecules and the ‘matrix’ molecules (alkanethiols). The shape of the ‘template’ molecules should be similar to the species studied but with additional thiol groups to provide strong binding to the surface; however, the ‘matrix’ molecules should adsorb strongly to the surface to form a monolayer thicker than that of the template molecules (**Figure 1**).

The extension of a 2D monolayer to a 3D ordered assembly represents the recent advances to prepare well-defined multilayers. Among several different approaches, a method based on the electrostatic interaction between oppositely charged species layer-by-layer has been widely used to build up a variety of multilayer assemblies with precisely controlled thickness and layer sequences. A novel strategy for controlled fabrication of a well-defined monolayer and multilayer film containing polyoxometalates (POMs) on a gold electrode covered with alkanethiol SAMs has been proposed (**Figure 2**). During the assembly process, the formation of the multilayer by using electrochemical growth has been proven to have

**Figure 2** Schematic illustration of deposition procedures and conceptual models of monolayers and multilayers consisting of POMs (large circles) and QPVP-Os (thin curves) on two kinds of positively and negatively charged precursor alkanethiol SAMs. Cysteamine (A) and 3-mercaptopropionic acid (B) SAMs on Au electrodes are typically used. Depicted are various stages of the film formation: (A1) Au/Cyst; (A2) Au/Cyst/POMs; (A3) Au/Cyst/3POMs/2QPVP-Os; (B1) Au/MPA; (B2) Au/MPA/QPVP-Os; (B3) Au/MPA/QPVP-Os/POMs; and (B4) Au/MPA/3QPVP-Os/3POMs. (Reprinted with permission from Cheng L, Niu L, Gong J, and Dong SJ (1999) *Chemistry of Materials* 11: 1465; © American Chemical Society.)

more advantages over the commonly used immersion growth. The tunable multilayer films prepared may find applications in sensors, catalysis, electrochromism, and other thin film molecular devices.

### Mono- and Multilayer Assembly on a Carbon Electrode

Beside properties of inertness and stability, carbon electrodes have a wide potential range when compared to gold electrodes, which are more popularly used in electrochemical laboratories and fuel cells. The modification of the carbon surface is of importance in electrocatalytic, analytical, and biotechnological applications.

In order to construct an ordered monolayer on a carbon surface, a premodified smooth and functionalized film is needed. Electrochemical reduction of diazonium salts or oxidation of amine-containing compounds and acrylate produces free radicals, resulting in covalent derivatization of the carbon surface in nonaqueous solutions (Figure 3). The premodification by free radical grafting methods is quite mild, simple, and rapid experimentally. The monolayers prepared as a precursor film for subsequent assembly are stable to harsh environments and can endure elevated temperatures, and especially are organized in order, compact, and charge-rich.

The premodification method has been proved to be a general one suitable for anchoring many kinds of organic and inorganic compounds, biomolecules,

and nanoparticles to construct ordered composite monolayers on carbon electrode surfaces. Starting from the obtained composite monolayer, a method based on electrostatic interaction between oppositely charged species, layer by layer, has been used to build up a variety of multilayer assemblies with precisely controlled thicknesses and layer sequences.

There are numerous research works on applications of catalysis and sensors by using the composite monolayer and multilayer modified carbon electrodes; for instance, NADH oxidation can be catalyzed at the dopamine grafted on glassy carbon (GC) electrode; determination of uric acid in the presence of 30-fold excess of ascorbic acid at GC electrode modified with cysteine layer by amine oxidation. The sensitivity ratio of chlorpromazine to uric acid is largely enhanced at the *p*-ethylphenyl monolayer grafted on the GC electrode; and a simple method for the fabrication of biotin-avidin based biosensors at the biotin immobilized on the GC electrode via amine oxidation is realized. Multilayer film systems based on 3D assembly on carbon electrode surfaces exhibit stronger activities, such as the multilayer films consisting of a cationic redox polymer QPVP-Os and POMs through layer-by-layer construction show high electrocatalytic activity on the reductions of  $\text{BrO}_3^-$ ,  $\text{IO}_3^-$ ,  $\text{HNO}_2$ , and  $\text{H}_2\text{O}_2$ ; organic-inorganic multilayer films composed of POMs ( $\text{P}_2\text{W}_{18}\text{O}_{62}^{6-}$ ) and metalloporphyrin ( $\text{CoTMP}_y\text{P}$ ) can catalyze  $\text{O}_2$  reduction mainly through  $4e^-$  to  $\text{H}_2\text{O}$ , whereas when using  $\text{SiW}_{12}\text{O}_{40}^{4-}$  instead of  $\text{P}_2\text{W}_{18}\text{O}_{62}^{6-}$ , the multilayer films exhibit high activity toward the hydrogen evolution reaction; a multilayer film constructed by vanadium-substituted POMs

**Figure 3** Some possible routes for the covalent modification of carbon surface using (A) amino, (B) diazonium, and (C) acrylate based compounds. ( $P_2W_{15}V_3O_{62}^{9-}$ ) with QPVP-Os can be used to detect ascorbic acid in the presence of dopamine; iron-substituted POMs ( $P_2W_{17}O_{61}Fe^{7-}$ ) with QPVP-Os formed multilayer films that give remarkable catalysis effects on  $H_2O_2$ ,  $BrO_3^-$ , and  $NO_2^-$  reactions.

Carbon nanotubes (CNTs) have attracted increasing attention from various fields recently. The high surface area and hollow geometry, combined with their high electronic conductivity and useful mechanical properties, show that CNTs have the ability to promote electron transfer when used as electrode material in electrochemical reactions. CNTs show a better electrochemical response when compared to ordinary carbon electrodes. One promising application of CNTs is their use in electrochemical sensors and nanoscale electronic devices. CNT electrodes have been utilized to detect: different types of analytes, some gas molecules such as NO,  $NO_2$ ,  $NH_3$ , small molecules such as dopamine, to catalyze biomolecules, and inorganic compounds. CNT electrodes were also successfully used in studying the electrochemistry of proteins. Chemically modified CNT electrodes with different functional groups would be more sensitive and selective in sensor application and catalysis. Recently, the CNTs/Nafion composite film immobilized on GC electrodes exhibited strong and stable electrocatalytic activity and electrogenerated chemiluminescence (ECL) of  $Ru(bpy)_3^{2+}$  responses to tripropylamine and oxalate. Based on the inhibition effect of dopamine on ECL of the above system, the determination of dopamine in the presence of ascorbic acid was realized. Interestingly, a hybrid thin film composed of CNTs/CoTMPyP/Pt on a GC electrode (Figure 4) shows remarkable electrocatalytic activity to oxygen reduction and high stability with promising application in fuel cells.

## Polymer Film Electrode

Polymer-based CMEs have been developed for analytical applications by either amperometric or potentiometric technique over the last decades. There are three kinds of polymers used extensively to prepare polymer film electrodes: (1) redox polymers; (2) ion-exchange and coordination polymers; and (3) electronically conductive polymers. Redox polymers contain electroactive functionalities either within the main chain or side groups pendent to the chain. Poly(vinylferrocene) is the typical example of redox polymers. Ion-exchange and coordination polymers can incorporate electroactive guest molecules although they are not electroactive themselves, for example, poly(vinylpyridine) film can incorporate electroactive counterions through an ion-exchange reaction. The perfluorosulfonate ionomer Nafion is the cation-exchange polymer used in extensive concentration and selective detection studies. Electrochemically conductive polymers contain electroactive chains. Their representatives like polyaniline, polypyrrole, and polythiophene are conjugative, and the cationic sites resulting from the oxidation would be delocalized along the polymer chain. This is in contrast to the case of a redox polymer like poly(vinylferrocene), where the positive charge produced during the oxidation would be localized within the ferrocene.

To prepare polymer film electrodes there are different techniques like dip coating, spin coating, electropolymerization from monomers, and molecularly imprinted polymers (MIPs) developed very recently. They are often used for both potentiometric and amperometric ion sensors. Some feature of different types of ion sensors based on polymer CMEs are shown in Table 1. Conducting polymer-based CMEs

**Figure 4** (A) AFM images: (a) MWNTs/CoTMPyP/PtCl<sub>6</sub><sup>2-</sup> film assembled on GC electrode (before electrochemical reduction); (b) MWNTs/CoTMPyP/Pt hybrid film (after electrochemical reduction at  $-0.7$  V in N<sub>2</sub>-saturated 0.1 mol l<sup>-1</sup> KCl solution). (B) XPS data of MWNTs/CoTMPyP film on GC surface (curves (a) and (b)) and MWNTs/CoTMPyP/PtCl<sub>6</sub><sup>2-</sup> film in the Pt (4f) region before (curve (c)) and after (curve (d)) electrochemical reduction. (Qu JY, Shen Y, Qu XH, and Dong SJ (2004) Preparation of hybrid thin film modified carbon nanotubes on glassy carbon electrode and its electrocatalysis for oxygen reduction. *Chemical Communications* 2004: 34–35; reproduced by permission of The Royal Society of Chemistry.)

can be well used in ion-selective electrodes (ISEs) for miniaturization.

The preparation of MIPs includes the formation of a complex between the functional monomer and guest molecules (template) in solution followed by freezing this complex through polymerization in the presence of high concentration of cross-linker. After removing the template by washing, the polymer

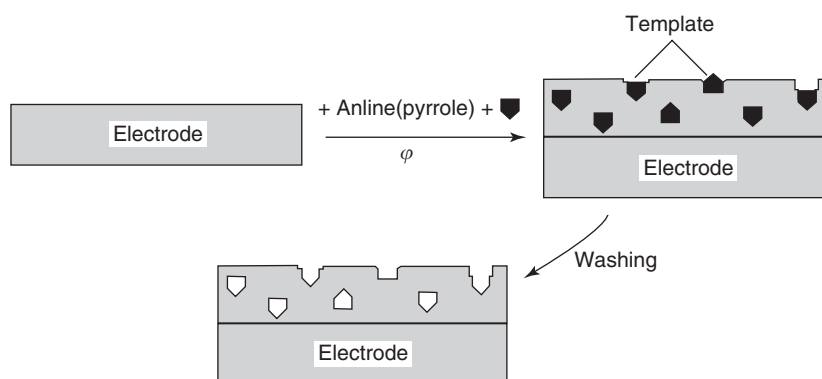

binding sites (imprints) are retained in the structure specifically for the template molecule. The preparation of MIPs can also be processed on the electrode surface by electropolymerization (Figure 5). This technique is convenient to deposit a sensitive layer with high precision on the electrode surface that can be used for various substances. This is also important for micro- and multisensor production.

**Table 1** Features of different types of ion sensors

Types of ISE	Structure	Fabrication methods	Sensitivity	Potential stability	Durability and miniaturizability
Conventional	L/ISM(I)	Solution casting	Ion	Excellent	Poor
CWE	S/ISM(I)	Solution casting	Ion	Poor	Good
SCISE	S/CP/ISM(I)	(1) Electropolymerization (2) Solution casting	Ion	Good	Good
SPISE	S/ISM(CP,I)	Solution casting	Ion/redox	Good	Good
CPISE	S/CP(I)	Electropolymerization or solution casting	Ion/redox	Good	Excellent

CWE, coated-wire electrode; SCISE, solid-contact ISE; SPISE, single-piece ISE; CPISE, conducting polymer-based ISE. L, aqueous electrolyte solution or hydrogel; ISM(I), ion-selective membrane containing ion-recognition sites (I); S, solid electronic conductor; CP, conducting polymer; ISM(CP, I), ion-selective membrane containing conducting polymer (CP) and ion-recognition sites(I); CP(I), conducting polymer containing ion-recognition sites(I).

Inorganic ions, drugs, nucleic acids, proteins, and even cells are successful examples of imprinting. In this way, affinity sensors, receptor sensors, and catalytic sensors based on MIPs have been explored. For affinity sensors, immunosensor-like devices were prepared by a 2D MIP technique with molecular imprinting on chemisorbed alkanethiol SAMs; then after necessary procedures, vitamins K<sub>1</sub>, K<sub>2</sub>, E, cholesterol, and adamantine could be detected by the strong electrochemical signals yielded. The sensors for nucleic acids, cholesterol, and catechol derivatives can be fabricated first by their adsorption as a template on the ITO surface and then by the treatment of the electrode with adsorbed template using trimethyl chlorosilane from the gas phase.

## Nanoparticle Modified Electrodes

Nanoparticles often display unusual physical and chemical properties mainly depending on their size

and shape, which have kindled much attention recently. Metal nanoparticles can act as catalyst, facilitate the electron transfer, and be modified with many biomolecules and ligands. All the properties permit obtaining a sensing interface that can be attached on the electrode surface. A nanoparticle modified electrode may be prepared by metal particles dispersed in a polymer film, in porous aluminum oxide film, with SAMs, or with films of porous glass based on sol–gel formation. Metal (especially Pt, Au) nanoparticles and their derivatives like monolayer protected clusters have extended applications in electroanalytical chemistry, for example, nonenzyme sensors and enzyme sensors. Gold nanoparticles with thiol derivatives as strong stabilizers can form a monolayer on the surface with strong coordination to modify metal nanoparticles with various organic ligands (**Figure 6**) for optical, chemical, and biosensing biomolecules (DNA) while retaining their activity. For nonenzyme sensors, metal nanoparticles or functionalized nanoparticles are used as sensing phase, while for enzyme

**Figure 6** Reactivity of monolayer-protected clusters: (A) place exchange, (B) reaction of *p*-mercaptophenol with propionic anhydride, (C)  $\text{S}_\text{N}^2$  reaction of bromoalkanethiolated MPCs with primary alkylamines, (D) amide and ester coupling reactions, (E) siloxane formation reactions, and (F) transition-metal-catalyzed ring-opening metathesis polymerization. (Reprinted with permission from Templeton AC, Wuelfing WP, and Murray RW (2001) Monolayer-protected cluster molecules. *Accounts in Chemical Research* 33: 27–36; © American Chemical Society.)

sensor, enzyme modified metal nanoparticles are used as sensing phase where nanoparticles act as mediators. For example, gold nanoparticles as the prepared

working electrode of the  $\text{SO}_2$  sensor catalyze the electrochemical oxidation of  $\text{SO}_2$ ; gold nanoparticles dispersed on the electrode surface can facilitate the

**Figure 7** Stepwise assembly of the three-dimensional array of organic oligocation-cross-linked Au nanoparticle superstructures on glass surfaces. (Reprinted with permission from Shipway AN *et al.* (2000) *Langmuir* 16: 8789; © American Chemical Society.)

electrooxidation of carbohydrates in alkaline media, which has been used as amperometric sensor for carbohydrates in flow injection and liquid chromatography; gold nanoparticles can also facilitate the electron transfer of redox proteins like horse heart cytochrome *c* and so forth. Another typical example in the selective electrochemical sensing of various substances like hydroquinone, ferrocene derivatives, adrenaline, dopamine etc., by the organization of layered gold nanoparticle architectures on ITO–glass support. It was processed by cross-linking the particles with oligocationic bis-bipyridinium cyclophene or molecular square transition-metal complex (Figure 7) where the organic cross-linker molecules act as receptors for  $\pi$ -donor substances, thus causing the concentration of such guests on the electrode.

Nanoparticle monolayers and multilayers can also be prepared directly by electrochemistry without performance of the nanoparticles. For example, Ag nanoparticles monolayer can be formed by  $\text{Ag}^+$  grafted on 4-aminophenyl monolayer on highly oriented pyrolytic graphite followed by pulse electroreduction, and then the uniformly dispersed Ag nanoparticles as ordered monolayers are prepared. By a similar design Pd and Pt ordered monolayers can also be fabricated. For Pt (or Pd) nanoparticle ordered multilayers, they can be assembled with  $\text{PtCl}_6^-$  (or  $\text{PdCl}_4^{2-}$ ) and CoTMPyP alternatively followed by electroreduction. The Pt or Pd nanoparticle ordered multilayers formed on the electrode surface demonstrate high catalytic activity to  $\text{O}_2$  and  $\text{H}_2\text{O}_2$  reduction.

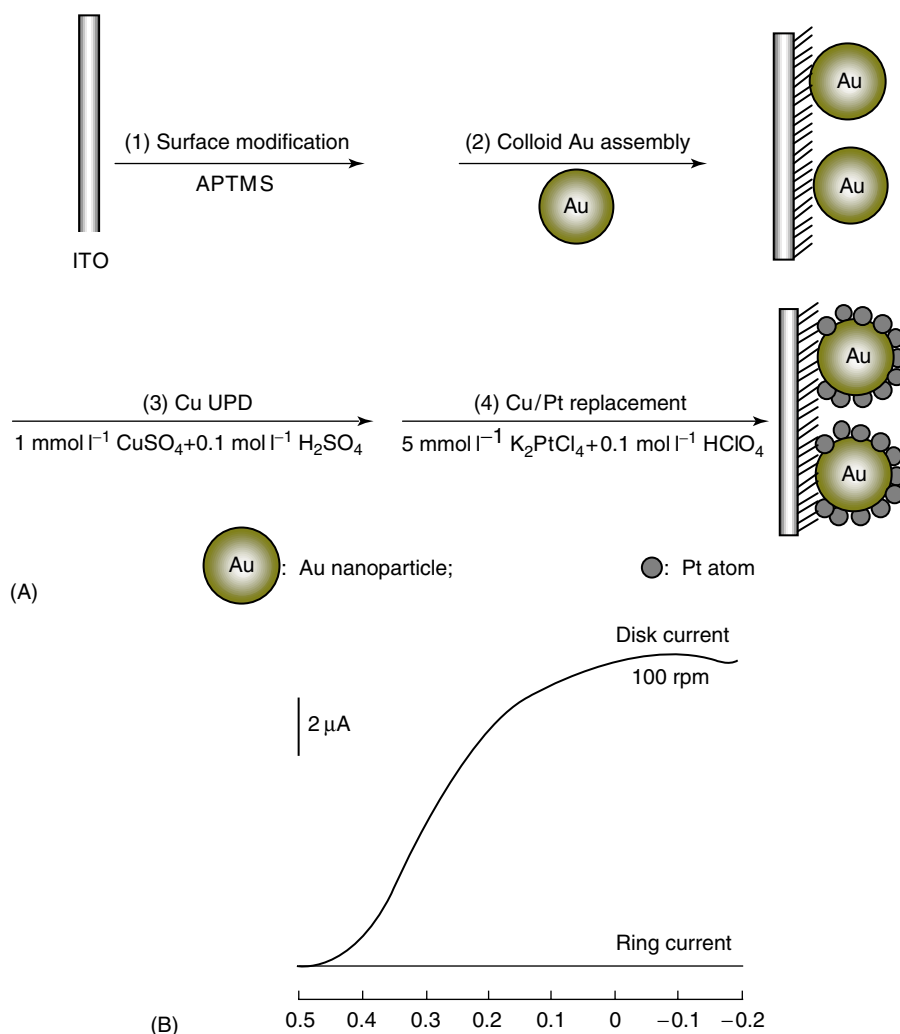

Another approach to prepare nanoparticle ordered multilayers by preceding the formation of the nanoparticle monolayer can be achieved by a bottom-up

way. A molecular cross-linker APTMS (a kind of amino-silane, (3-aminopropyl)-trimethoxysilane) layer is first modified on the solid substrate (e.g., ITO), and then the nanoparticles monolayer is assembled. The organization of a gold nanoparticle multilayer on ITO by using oligocationic bis-bipyridinium cyclophene or molecular square transition-metal complexes through cross-linking the nanoparticles has been achieved (Figure 7). Similarly, the nanoparticle ordered multilayer can be assembled alternatively by ‘molecular gels’ (dithiols, dipyrindinium, diamino, and thio-containing molecules) and nanoparticle sol. For example, on ITO electrode the thionine dye molecule bridged nanoparticle multilayers demonstrate porosity, permeability, and 3D conductivity.

Enzyme sensors are another important application of metal nanoparticles in CMEs besides nonenzyme sensors. Many enzymes can keep their activity when anchored onto gold nanoparticles. A novel method for fabrication of a biosensor based on the combination of sol–gel and self-assembled techniques has been introduced very recently. For example, the gold nanoparticles and enzyme horseradish peroxidase (HRP) can be successfully immobilized on gold electrode by the help of sol–gel with thiol groups, and the direct electrochemistry of HRP has been achieved and the biosensor thus prepared exhibits fast response, good reproducibility, and long-term stability.

Using underpotential deposition with the redox replacement technique a novel electrochemical approach for nanoparticle-based catalyst has been designed. Here, the as-prepared Pt-coated Au nanoparticle monolayer at atomic level on the electrode surface can reduce  $\text{O}_2$  predominately by 4e to  $\text{H}_2\text{O}$ , which was confirmed by rotating ring disk electrode technique (Figure 8).

**Figure 8** (A) Schematic illustrations of preparation procedures of ultrathin (nominally monolayer level) platinum-coated gold nanoparticle monolayer films on an ITO electrode surface. (B) Current–potential curves for the reduction of air-saturated  $\text{O}_2$  at a rotating platinum ring-graphite disk electrode with ultrathin Pt-coated Au nanoparticles monolayer adsorbed on the disk electrode. The potential of the ring electrode was maintained at 1.0 V. Rotation rate: 100 rpm. Scan rate:  $50 \text{ mV s}^{-1}$ ; supporting electrolyte:  $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ . (Reprinted with permission from Jin YD, Shen Y, and Dong SJ (2004) Electrochemical design of monolayer-level platinum-coated gold core-shell nanoparticles monolayer films as novel nanostructured electrocatalysts for oxygen reduction. *Journal of Physical Chemistry B*, in press; © American Chemical Society.)

### Introduction

The exploitation of microorganisms for sensing purposes covers a wide range of applications. In the most general case, a microorganism or consortium of microorganisms is exposed to a test environment and the effect(s) of exposure are compared to a control environment using any one of a number of measures. Such approaches might be divided into three broad areas:

- traditional microbial assays, using classical microbiological methods, e.g., cell counting;
- microbial assays using close coupling with physicochemical methods of transducing the signal, e.g., luminometer; and
- integration of microorganisms with physicochemical transduction methods, e.g., electrochemical biosensors.

The term ‘biosensor’ has been used loosely to describe all of these situations, but this article considers only those situations where the microorganisms are integrated with a transducer or the microorganisms are genetically modified and then used in close coupling with a transducer.

The exploitation of microorganisms as the biological component in biosensors is not as advanced or as widespread as the use of biomolecular biocatalysts in enzyme- and antibody-based biosensors. However, the stability of intact cells and the great diversity of microbial species enable the development of biosensors for use in a range of applications, including analyte determination in complex mixtures, process control, environmental monitoring, toxicity assessment, and mutagen detection. Electrochemical transducers dominated the earlier sensor types used to incorporate microbial cells, with amperometric oxygen electrodes and potentiometric ion-selective electrodes (ISEs) accounting for the majority of devices. Optical transducers, however, are becoming more

prevalent, with a wide variety of fluorescence- and luminescence-based devices having been described – particularly related to those sensors incorporating genetically modified organisms.

Monitoring of changes in (1) the level of microbial metabolic activity or (2) the concentration of products from microbial biotransformation, of specially selected biocatalysts, can provide rapid analysis or determination of sample quality. Whilst microbial-based sensors are able to demonstrate good sensitivity, they do not possess the inherent selectivity of enzyme- or antibody-based sensors. Therefore, the most promising areas for microbial biosensors will probably be in broad spectrum monitoring or those applications where specificity is not a problem. The recent scientific literature shows continuing interest in the use of microorganism-based sensors for environmental monitoring (particularly the development of rapid methods for estimation of biological oxygen demand, BOD). Recent global security issues also suggest new opportunities for such biosensors.

### Principles

#### Microbial Cells as Sensor Biocatalysts

A wide range of microorganisms have been used as biocatalysts. Bacteria dominate but cyanobacteria, microfungi, protozoa, and microalgae have all been successfully used in biosensors. Whilst living cells have many benefits as biocatalysts they also pose unique problems and these need to be successfully overcome before microbial-based sensors can become commercially successful. Six major benefits can be identified:

- high degree of stability, incorporating complete metabolic systems within a protected environment, and possessing damage repair capabilities allowing *in situ* recovery;
- wealth of known species covering many metabolic types, with a wide range of sensitivities and nutritional requirements;
- ability to perform complex reaction sequences;
- ease of maintenance in pure culture, low harvesting, and production costs;

### Introduction

The exploitation of microorganisms for sensing purposes covers a wide range of applications. In the most general case, a microorganism or consortium of microorganisms is exposed to a test environment and the effect(s) of exposure are compared to a control environment using any one of a number of measures. Such approaches might be divided into three broad areas:

- traditional microbial assays, using classical microbiological methods, e.g., cell counting;
- microbial assays using close coupling with physicochemical methods of transducing the signal, e.g., luminometer; and
- integration of microorganisms with physicochemical transduction methods, e.g., electrochemical biosensors.

The term ‘biosensor’ has been used loosely to describe all of these situations, but this article considers only those situations where the microorganisms are integrated with a transducer or the microorganisms are genetically modified and then used in close coupling with a transducer.

The exploitation of microorganisms as the biological component in biosensors is not as advanced or as widespread as the use of biomolecular biocatalysts in enzyme- and antibody-based biosensors. However, the stability of intact cells and the great diversity of microbial species enable the development of biosensors for use in a range of applications, including analyte determination in complex mixtures, process control, environmental monitoring, toxicity assessment, and mutagen detection. Electrochemical transducers dominated the earlier sensor types used to incorporate microbial cells, with amperometric oxygen electrodes and potentiometric ion-selective electrodes (ISEs) accounting for the majority of devices. Optical transducers, however, are becoming more

prevalent, with a wide variety of fluorescence- and luminescence-based devices having been described – particularly related to those sensors incorporating genetically modified organisms.

Monitoring of changes in (1) the level of microbial metabolic activity or (2) the concentration of products from microbial biotransformation, of specially selected biocatalysts, can provide rapid analysis or determination of sample quality. Whilst microbial-based sensors are able to demonstrate good sensitivity, they do not possess the inherent selectivity of enzyme- or antibody-based sensors. Therefore, the most promising areas for microbial biosensors will probably be in broad spectrum monitoring or those applications where specificity is not a problem. The recent scientific literature shows continuing interest in the use of microorganism-based sensors for environmental monitoring (particularly the development of rapid methods for estimation of biological oxygen demand, BOD). Recent global security issues also suggest new opportunities for such biosensors.

### Principles

#### Microbial Cells as Sensor Biocatalysts

A wide range of microorganisms have been used as biocatalysts. Bacteria dominate but cyanobacteria, microfungi, protozoa, and microalgae have all been successfully used in biosensors. Whilst living cells have many benefits as biocatalysts they also pose unique problems and these need to be successfully overcome before microbial-based sensors can become commercially successful. Six major benefits can be identified:

- high degree of stability, incorporating complete metabolic systems within a protected environment, and possessing damage repair capabilities allowing *in situ* recovery;
- wealth of known species covering many metabolic types, with a wide range of sensitivities and nutritional requirements;
- ability to perform complex reaction sequences;
- ease of maintenance in pure culture, low harvesting, and production costs;

- high levels of catalytic activity achieved with modest loading levels; and
- amenable to genetic manipulation, offering the possibility of specific trait incorporation and biocatalyst 'tailoring' for specific applications.

Whilst in the biosensor research laboratory these benefits can be exploited to the full, problems arise in developing sensors incorporating microorganisms that can be produced commercially. Central to this is the need to develop methods of handling microorganisms during fabrication and bulk production of biosensors. In particular, further development is required for:

- harvesting of cells in the appropriate metabolic state;
- appropriate immobilization techniques; and
- preservation methods to give good shelf life.

Optimization of these factors is required so as to enable batch consistency, stability, and extended operational life of the biosensor. These requirements are easier to satisfy with bacterial species, than with protozoa, algae, or fungi.

### Monitoring Biological Response

Unlike the biocatalytic or bioaffinity components of enzyme- and antibody-based biosensors, living microbial cells undertake a vast range of biochemical processes and respond to a multitude of physiological events. Monitoring of a microbial biocatalyst can therefore be directed at specific cellular events or at total metabolic activity. Present technology allows only a limited range of interrogation methods for use with living cells, and the full potential of microbial biosensors will only be achieved when a wider range of techniques are developed allowing nondestructive targeting of specific cellular events *in vivo*.

The majority of devices employ one of the following three electrochemical approaches to monitoring the biological component:

- monitoring oxygen or carbon dioxide to follow respiratory or photosynthetic activity;
- detection of metabolic products other than carbon dioxide or oxygen; and
- using redox mediators to monitor respiratory or photosynthetic activity.

Calorimetric methods can also be applied, exploiting the thermal changes that accompany enzymatic reactions within the microbial biocatalyst to monitor metabolic activity levels.

Transducer monitoring of microbial activity has many advantages over conventional microbial bioassay techniques, in particular:

- rapid response and assay/test times, often 15 min or less;
- ease of use by nonspecialists;
- lower assay cost; and
- potential for field-based testing and online use.

### Types of Biological Response

**Determination of specific analytes** The rapid response of bacterial cells to the appearance of respiratory substrates in their environment was the first feature exploited in microbial biosensors. Monitoring oxygen uptake of a heterotrophic species by means of the Clark oxygen electrode, it is possible to determine accurately the substrate concentration, over a limited range, from the respiratory response of the biocatalyst. Respiratory activity can also be monitored using carbon dioxide probes, mediated amperometry or calorimetry.

Unlike enzyme-based biosensors such responses are subject to interference from a large number of other compounds to which the microbial biocatalyst would respond. Determination of the concentration or presence of specific analytes in mixtures is therefore difficult, although several approaches to overcome this problem have been employed including: careful biocatalyst selection; biocatalyst conditioning or induction; and the use of inhibitors to suppress unwanted systems.

Alternatively, it is sometimes possible to gain some degree of selectivity by monitoring selected metabolic events within the cell, rather than total metabolic activity. The use of ISEs to detect product formation from a particular metabolic event can be used to determine the presence and concentration of substrates. Ammonia gas sensors have been used to detect deamination by bacterial cells for the determination of amino acids. However, the development of microbial biosensors capable of specific amino acid detection has to overcome the problem of interference from other amino acids and related compounds.

Developments in molecular biology have enabled the exploitation of genetically modified microorganisms to provide appropriate sensitivity to external analytes. Typically, there are two applications of genetically modified microorganisms in biosensor configuration – broad spectrum or analyte specific. In both cases the microorganism is genetically modified by the introduction of an appropriate reporter gene, whose expression is easily detected and monitored. In the majority of cases these are light

emitting or fluorescent reporter genes from either bacteria, for example, green fluorescent protein (*Aquorea victoria* gfp) or bioluminescence (*Vibrio fischeri* lux) genes, or the light emitting *luc* gene from the firefly. Microorganisms incorporating light-emitting reporting genes can be used in broad spectrum biosensors to monitor the metabolic status of the cell and respond to changes in substrate level or toxic challenge. Analyte specificity has been achieved in biosensors exploiting microorganisms that incorporate reporter genes linked to selected promoter genes triggered by the presence of specific analytes such as heavy metal ions (e.g., mercury and cadmium). Incorporation of additional genetic components has also been used to provide an internal reference signal so as to correct analytical responses due to nonspecific interferences.

The future use of analyte-specific microbial biosensors is likely to be in those situations where biomolecular-based sensors are impractical – for reasons of availability, stability, or cost.

**Broad spectrum analysis** The ability of microorganisms to respond to a wide range of materials can be a positive advantage, enabling their use in situations where analyte specificity would be a disadvantage. The monitoring of metabolic stimulation associated with substrate presence has been used in such applications as the monitoring of fermenter liquor substrate profiles. The recent scientific literature shows a continuing interest in the development of rapid methods for the estimation of BOD since the conventional 5-day BOD<sub>5</sub> is not suited to process control – for example, in waste water treatment plants for environmental protection.

In some situations it may be appropriate to use single-species biocatalysts where the response profile is known to match the expected analyte composition of the sample or environment to be monitored. In other situations it may be desirable to have as broad a response as possible in order to allow the detection of both the expected and unexpected. In these latter cases, a number of different microbial species may be used either in multisensor arrays or as a mixed microbial population incorporated into the sensor.

These different types of configuration are also appropriate for use in the detection of potentially toxic or mutagenic species. The use of microbial bioassays for mutagenicity and toxicity testing is now well established, and the coupling of such tests with appropriate transducers shows promise for rapid testing. In these applications, the metabolic activity of the microbial biocatalyst is monitored for signs of perturbation caused by the presence of cytotoxic or genotoxic chemicals. Recent developments in global

security issues suggest potential for development of microorganism-based sensing systems to be deployed at sensitive sites for the detection of chemical and biological terrorist attacks.

## Sensor Design

The choice of biocatalyst, transducer, and method of biocatalyst immobilization all influence sensor design, and many different combinations of microbial biocatalysts and transducers have been investigated.

### Configuration of Biocatalyst and Transducer

The preferred biosensor configuration for most applications is the electrode type, with intimate contact between the biocatalyst and the transducer element. Microorganism-based biosensors initially exploited existing ‘off-the-shelf’ electrochemical transducer electrodes and developed different strategies to incorporate the biological component. Whilst this approach was convenient for investigating biocatalyst response and exploring potential applications, conventional electrodes are large and expensive. For most applications the electrodes, incorporating the biocatalyst, need to be manufactured in bulk and at a cost appropriate for single-use disposable units.

In those cases where the transducer element does not lend itself to bulk manufacture and disposal after use, an alternative approach is to arrange for the biological component to be incorporated in a low-cost disposable unit, with a simple method for replacement when necessary. This is particularly suitable for flow-through-type measurement systems, where the biocatalyst can be upstream of the transducer – as in the flow-injection analysis (FIA) approach to monitoring.

Some microbial biomonitors have been described where the biological component is in the form of a cell suspension in a stirred reactor and the electrodes are immersed in the reactor liquid to monitor changes in parameters such as pH,  $pO_2$ , or  $pCO_2$ . Whilst this approach has much in common with microorganism-based sensors it is not appropriate to use the term biosensor for such devices.

### Biocatalysts

There is often a choice of microorganisms that can be considered for use in any particular application. This can be seen with commonly addressed applications for microbial biosensors such as the determination of single components, e.g., glucose or ethanol, or the detection of toxic pollutants, e.g., atrazine or pentachlorophenol (PCP). Many microorganisms could be selected for such applications, as a wide range of

microorganisms are able to utilize glucose or ethanol, while atrazine and PCP are toxic to most microorganisms. Even where unusual substrate detection is required, many bacterial and fungal species can be conditioned to utilize such compounds. Unlike enzyme- and antibody-based biosensors, microbial biosensors are not restricted to one or a very few biocatalysts for a particular application.

Ultimate selection of biocatalysts depends on several factors:

- screening tests for most responsive/sensitive species, using both conventional bioassay methods and biosensor monitoring;
- identification of the biocatalysts most conducive to monitoring using transducer technology;
- biocatalyst stability in the biosensor configuration;
- amenability to *in situ* preservation.

### Transducers

The majority of microbial biosensors employ one or other of the following transducer elements.

**Oxygen electrodes** The incorporation of an immobilized layer of microbial cells onto the outer surface of the polytetrafluoroethene (PTFE) membrane of a Clark amperometric oxygen electrode allows depletion of oxygen in the microbial layer due to changes in respiratory activity to be monitored continuously. Standard oxygen electrodes are most frequently used (Figure 1), but smaller and cheaper electrodes can be produced, typically using screen printing or microfabrication techniques.

**Figure 1** Biosensor assembly based on the Clark oxygen electrode. A, dialysis membrane; B, bacteria-loaded tortuous filter; C, PTFE membrane; D, platinum electrode; E, 'O' ring; F, silver/silver chloride electrode; G, potassium chloride solution.

**Potentiometric electrodes** Ammonia or carbon dioxide gas sensing probes can be employed in the same way as the oxygen electrode, with the immobilized microbial layer held in place on the surface of the gas-permeable membrane. The ammonia probe is commonly used to determine amino acids by detection of ammonia production by microbial deamination of amino acids. Carbon dioxide probes are alternatives to oxygen electrodes for monitoring respiratory activity.

**Mediated amperometric electrode** Redox mediators such as the ferricyanide ion, *p*-benzoquinone, or dimethylferrocene can be used as electron carriers allowing redox events within the cell to be monitored using suitably poised electrodes (Figure 2). Mediator reduced by enzymatic events within the cell is reoxidized at the working electrode surface resulting in a current flow. This technique has been successfully applied to the monitoring of bacterial and cyanobacterial respiratory and photosynthetic activity using nonmembrane-penetrating mediators to monitor dehydrogenase activity of the plasmalemma. Mediated amperometry can be applied to both probe and FIA-type configurations.

**Luminescence or fluorescence** A wide variety of microorganisms is naturally bioluminescent and/or has been genetically manipulated to incorporate genes encoding for proteins that bring about bioluminescence. In the simplest cases, the intensity of light emission is measured in cuvettes in a conventional luminometer. In other cases, the microorganisms may be attached to fiber optic cables.

Fluorescence is similarly used for monitoring microbial activity. Chlorophyll fluorescence is widely used to monitor cyanobacteria or algae, while the incorporation of genes encoding for green fluorescent protein (gfp) or other fluorescent probes allows a wide variety of cell types to be monitored this way. Most conveniently, the cells are coupled to a fluorimeter using an optical fiber cable.

### Biocatalyst Immobilization

Physical entrapment is the most common method of immobilization, and this can take several forms:

- capture on tortuous or nontortuous filter discs held in place on the electrode/probe by dialysis or similar membranes;
- entrapment within a polymer matrix, such as calcium alginate, carrageenan, or collagen;

**Figure 2** Electron transfer events at the surface of a mediated amperometric bacterial biosensor, showing mediators assessing redox sites on the cytoplasmic membrane and within the cell.  $M[ox]$ , oxidized mediator;  $M[red]$ , reduced mediator.

- cell suspensions trapped between the PTFE membrane of an oxygen electrode or ISE and an outer semipermeable membrane.

Membrane immobilization gives the best accuracy of loading, whilst the use of cell suspension is the most difficult method for achieving reproducible loading. Where the biocatalyst is upstream of the transducer element there is scope for a wide range of immobilization methods. Most systems employ microreactors of the packed bed or filter support type. This approach also allows much biocatalyst to be loaded at much higher levels than does the probe type of approach to sensor systems.

## Performance

A considerable number of analytes have been detected by microbial biosensors (Table 1). The overall performance of these biosensors needs to be compared to other analytical methods before any judgment on their suitability for the task can be made. Microbial biosensors are of most interest when they offer unique capabilities or significant advantages in the areas of cost and/or ease of use. Some examples of typical performance profiles are given below.

### Single-Component and Analyte-Specific Determination

The simplest type of analysis is that where only one component is present and the sensor is being used to

determine concentration. Here, interference from other chemical species is not a problem, and microbial sensors perform well in this situation. However, when specificity is required to allow analyte detection in complex mixtures of unknown composition interfering chemical species can become a problem.

Bacterial biocatalysts incorporated on to oxygen electrodes and ISEs typically have response times to analytes of between 5 and 15 min and show good stability for 7–30 days with storage normally in buffered saline between assays. Limits of detection and detection ranges are often similar to, or overlapping with those of, enzyme-based systems, such as the examples given below.

Glucose determination by

glucose oxidase biosensor (oxygen electrode, low concentrations; pH electrode, high concentrations):

$$1 \times 10^{-5} - 7 \times 10^{-1} \text{ mol dm}^{-3}$$

*Ps. Fluorescens* oxygen electrode:

$$1 \times 10^{-5} - 1 \times 10^{-4} \text{ mol dm}^{-3}$$

*Saccharomyces cerevisia* CO<sub>2</sub> electrode:

$$1 \times 10^{-3} - 1 \times 10^{-2} \text{ mol dm}^{-3}$$

Glutamine determination by

glutaminase biosensor:

$$1.5 \times 10^{-4} - 3.3 \times 10^{-3} \text{ mol dm}^{-3}$$

*Sarcina flava* ammonia gas ISE:

$$1 \times 10^{-4} - 1 \times 10^{-2} \text{ mol dm}^{-3}$$

These two examples also show good specificity for the target analyte, but many microbial biosensors

<sup>a</sup> BOD, biological oxygen demand.

respond to several compounds limiting their application for specific analyte detection. An *Acetobacter pasteurianus* based oxygen electrode has been used for the determination of lactic acid, and shows good stability for 6 days, with a linear response range of  $1 \times 10^{-4}$ – $1.5 \times 10^{-3}$  mol dm<sup>-3</sup>. Whilst the sensor was insensitive to lactose, sucrose, and glucose, it responded with similar sensitivity to pyruvic acid,

acetaldehyde, ethanol, ammonium acetate, and sodium acetate as well as to L- and D-lactic acids.

Enhanced selectivity and sensitivity has been achieved in two ways: (1) induction of the desired metabolic or membrane transport systems, or (2) the inhibition or suppression of undesired systems. The former method has been successfully used for phenolics (*Trichosporon cutaneum*), tyrosine

(*Aeromonas phenologenes*), and lactate (*Hansenula anomala*). The inhibition of systems has proven successful in pyruvate monitoring (*Streptococcus faecium*) by inhibiting glycolysis with iodoacetamide and tyrosine decarboxylase with tyramine, and in microbial detection of glutamic acid (*Bacillus subtilis*) treated with chloromercuribenzoate and sodium fluoride to inhibit glucose uptake and metabolism.

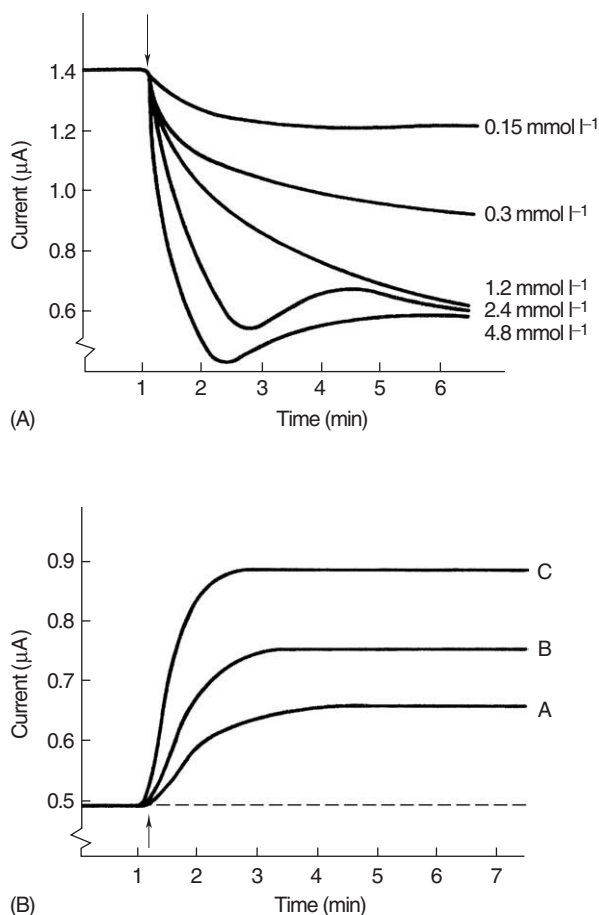

In comparison to enzyme-based biosensors, microbial biosensors show lower analyte selectivity, slightly slower response times, but often much better stability. Microbial biosensor determination of analytes such as amino acids, alcohol, and lactate show sensor stability over several days, whilst enzyme-based sensors may have operational lives of only 2–24 h.

### Broad Spectrum Monitoring

**Substrates** Monitoring total metabolic substances such as assimilable sugars or detecting the appearance/presence of potentially toxic compounds are applications ideally suited to microbial biosensors. In the case of substrates, *Brevibacterium lactofermentum* loaded oxygen electrodes have been operated for 10 days and up to a 1000 assays monitoring total glucose ( $<1 \text{ mmol l}^{-1}$ ), fructose ( $<1 \text{ mmol l}^{-1}$ ), and sucrose ( $<0.8 \text{ mmol l}^{-1}$ ) profiles in fermentation broth during glutamic acid production. In such situations the microbial biocatalyst mimics the fermenter organism and responds in much the same way to changes in substrate profiles. Typical responses obtained with bacteria loaded oxygen electrodes to a range of glucose concentrations are shown in Figure 3A.

**Toxicants** The use of microbial biosensors for detection of toxic or potentially toxic compounds is a recent development and one where the broad sensitivity of the microbial biocatalyst is vital. As toxicity is a biological phenomenon there is a need for intact organisms to be used in any such detection/assessment. In monitoring for toxicants there are positive advantages in following total metabolic activity or events that have an integrating effect on the metabolic events within the cell. Monitoring respiratory or photosynthetic activity for signs of perturbation has been used successfully to detect the presence of toxicants, using both mediated amperometric and oxygen electrode systems (Figure 3B).

Mediated amperometric biosensors incorporating bacterial and cyanobacterial biocatalysts have been shown to be sensitive to xenobiotics at environmentally relevant concentrations, enabling the biosensors to be used both for detecting toxic pollutants and

**Figure 3** (A) Typical current–time response curves of a bacterial oxygen electrode for a range of glucose concentrations. (↓) Glucose additions to the buffered minimal bathing medium. (B) Idealized current–time response curves for a bacterial oxygen electrode following the addition (↑) of toxicant solutions of different concentrations ( $A < B < C$ ) to the substrate supplemented bathing medium.

also for toxicity assessment. Sensitivity of detection increases with the toxicity of the analyte as shown by the inhibition of response of the mediated *Escherichia coli* biosensor to chlorinated phenols and biocides (Table 2). The magnitude of response to a single toxicant is determined by its concentration, as shown in the response to hypochlorite exhibited by biosensors incorporating a microbial consortium from activated sludge (Figure 4).

The hexacyanoferrate(III) mediator used in both examples accesses dehydrogenase enzymes on the bacterial outer membrane, and the biosensor signal reflects the concentration of reductant of the cells. Stimulation of the biocatalyst was by a cocktail of substrates. Both systems have operational lives of 3–5 days, being capable of continuous online applications, and response times of 15–30 min.

Toxicity screening by detection of respiration inhibition in *E. coli* has also been achieved by

**Table 2** Sensitivity of *E. coli* to chlorophenols and biocides

Toxicant	EC <sub>50</sub> <sup>a</sup> (mg l <sup>-1</sup> )	Limit of detection (mg l <sup>-1</sup> )
Mercuric chloride	0.41	0.027

<sup>a</sup> Effective concentration resulting in a 50% decrease in biosensor response.

<sup>b</sup> 4-Chloro-2-methyl-phenoxyacetate.

—, Information not available.

**Figure 4** Normalized responses of mediated amperometric biosensors, incorporating a microbial consortium from activated sludge from a wastewater treatment plant, to increasing concentrations of hypochlorite. The figure shows the 'best curve fits' of three electrodes (one from six replicates at each hypochlorite concentration) exposed at time zero to 20, 30, and 50 ppm hypochlorite, compared to the normalized controls (0). The results from a full 32 electrode test gave effect concentrations for hypochlorite of EC<sub>10</sub> = 5.3 ppm; EC<sub>50</sub> = 25.5 ppm; and a 'no observed effect concentration' (NOEC) = 0.14 ppm.

incorporating the bacterium immobilized on filters on to a carbon dioxide electrode. Carbon dioxide production in glucose-enriched buffer in a stirred vessel quickly reaches a steady state, and the addition of a toxicant is easily detected by the resultant fall in carbon dioxide production within the bacterial layer. This electrode showed good stability, with constant response over 1 week, and the biosensor was still

functional after 6 weeks of storage in phosphate buffer at 5°C. Toxicant concentrations causing a 40% inhibition of respiration included hydrogen cyanide (3.5 mg l<sup>-1</sup>), cadmium (0.3 mg l<sup>-1</sup>), lead (0.13 mg l<sup>-1</sup>), and copper (1.1 mg l<sup>-1</sup>).

The use of microorganisms in mutagenicity tests suggests that microbial biosensors might also be capable of screening for mutagens. Revertant strains of *Salmonella typhimurium* and *E. coli*, and a Rec-strain of *Bacillus subtilis* have been used in combination with dissolved oxygen sensors to detect mutagens and carcinogens. Mutagen concentrations as low as 0.001 µg dm<sup>-3</sup> were achieved with an *S. typhimurium* sensor using a 10 h incubation period.

## Applications

Microorganism-based sensors bring the advantages of both classical bioassay techniques and sensor technology to analytical investigations, and in particular allow exploitation of the ability of microbial cells to respond to a wide range of metabolic substrates and inhibitors at low concentration in aqueous solution. Discrimination between different utilizable substrates in the same sample can be achieved but with difficulty. The use of microbial biosensors is better suited to applications where there are no such problems of interference or any need for high selectivity.

Where the determination of a single analyte or group of analytes is sought, it will be necessary to know the nature of possible interfering chemical species and the likelihood of any such material being present in the sample. The use of a microbial biosensor will be compromised if undesired components to which the biosensor will respond are expected in the sample, unless selectivity can be improved by pretreatment or conditioning of the biocatalyst.

## Process Control

Despite these potential problems, many microbial biocatalysts have been identified with sufficient selectivity and sensitivity to allow their use in single analyte determination. The low cost, stability, and ease of use makes such analyses attractive. The most commonly reported application for such sensors is process control, both in fermentation and downstream monitoring. A wide range of fermentation products have been monitored by microbial biosensors including alcohols, amino acids, antibiotics, organic acids, peptides, and vitamins.

Monitoring of fermentation substrate profiles is also possible with microbial biosensors, both for single analyte determination (e.g., glucose, acetic acid)

or for multianalyte determination such as total assimilable sugars. In the latter case, the broad spectrum response of the microbial biocatalyst is a distinct advantage, and bacterial biosensors are well suited to such profile monitoring. The high concentrations of substrates in fermenter liquor may require a dilution step before samples are presented to the biosensors. This dilution step has the advantage of facilitating modification of the small sample volumes drawn from the fermenter, allowing such steps as the adjustment of oxygen concentration, pH, salinity, and addition of mediator.

### Environmental Monitoring

The sensitivity of microorganisms to environmental pollutants makes them ideal for exploitation in biosensors for monitoring environmental quality. Monitoring both stimulation and inhibition of microbial metabolism allows their application in areas such as BOD determination, pollution incident detection in surface waters, measurement of effluent quality, and toxicity assessment. Biosensors incorporating living cells are unique amongst sensors in being able to detect analytes on the basis of their toxicity and assess toxicity levels; their use is a natural extension of microbial ecotoxicity testing. Similarly, biosensor determination of BOD is a logical development of the 5-day test using oxygen electrodes to monitor microbially seeded vessels. Along with the advantages of low cost and rapid test methods, biosensors also allow field testing and can be designed for online continuous monitoring. The most promising role for such biosensors in environmental monitoring is that of prescreening, with an alarm signal generated by the biosensors resulting in sample capture and offline analysis by more conventional technology.

### Introduction

A photometric (or optical) sensor can be described as a device which can be employed for the detection and determination of physical and chemical parameters through measurements of optical property. Optical methods have played a dominant role and continue

to do so in various fields of analytical sciences. Chemical and biochemical analytes have been qualitatively detected by spot tests using spectroscopic techniques including colorimetry and photometry. Such techniques, in conjunction with the use of dry reagent chemistries, have revolutionized the field of optical chemical sensing, particularly in the field of clinical analysis. A very familiar example of a photometric sensor is the pH indicator strip, which utilizes immobilized pH-sensitive reagents on cellulose for qualitative measurements of pH over a wide

range. A major breakthrough was achieved when conventional spectroscopic analytical techniques were interfaced with optical fibers, which are offshoots of telecommunication industry. Optical fibers allow transmission of light over great distances and for chemical sensing typical monitoring distances required range from 1 to 100 m. In addition availability of low-cost optoelectronic components such as light-emitting diodes (LED), laser diodes, photodetectors, etc., and of rapid data acquisition and data processing techniques including chemometrics, has made considerable impact on the growth of and interest in optical chemical sensors over the past two decades.

Photometric chemical sensors based on optical fibers offer several advantages in various fields of application. These sensors are capable of observing a sample in its dynamic environment, no matter how distant, difficult to reach, or hostile this environment is. These devices are (1) intrinsically safe, involving a low optical power and are nonelectrical at the sensing point, (2) electrically passive and immune to electromagnetic disturbances, are geometrically flexible and corrosion resistant, (3) capable of being miniaturized, and (4) compatible with telemetry. Furthermore, the possibility of multiplexing several sensors to a single instrumentation unit can afford substantial economic advantages to this type of chemical sensor system. These features impart to the sensor immense potential importance in biomedical, process, and environmental monitoring applications.

Optical sensors possess more than a few limitations, which may need to be overcome if they are to replace existing sensor devices such as electrochemical sensors. The equilibrium involved in the chemical transduction restricts the concentration range over which the photometric sensors will be effectively useful. The dynamic range of optical sensors that have been studied to date extend over one or two orders of magnitude and, thus, a series of chemical transducers will be required in order to sense a single analyte at widely different levels of concentration. In such cases, a multisensor array system could be employed to widen the measurement dynamic range. In some chemical transduction systems, the equilibrium involved limits the reversibility characteristics of optical sensors. Ideally, these sensors should be capable of continuous use. However, in systems where a reaction is involved, the equilibrium state favors the formation of products which results in the consumption of the reagent by its conversion to some other form; in some cases the reagent can be regenerated using another chemical reaction. Another limitation is the response time of

spectroscopic sensors. Rates of chemical reactions and of diffusion of analytes and other materials determine the time taken for the attainment of a steady state in the chemical transduction system. Again the membrane, normally used as an envelope for the reagent phase, offers a barrier to mass transfer and contributes to response time. The lifetime of an optical sensor is determined by the stability of the reagent phases utilized in the chemical transducer particularly the photodecomposition characteristics of some of the reagents.

This article will review the practical methodology as applied to photometric sensors where measurements are confined to the ultraviolet and visible region of the electromagnetic spectrum. A previous article in this series on 'Sensors' has similarly discussed fluorescence measurement based sensors.

## Spectroscopic Techniques

In a photometric (optical) sensor, the optical property measured can be absorbance, reflectance, scattering, or emission. The first three of these methods of measurements are discussed in the following sections.

### Absorbance

The change in light intensity in an absorbance measurement is determined by the number of absorbing species in the optical path and is related to the concentration ( $C$ ) of the absorbing species via the Beer-Lambert relationship

$$A = \log_{10} \frac{I_0}{I} = \epsilon b C \quad [1]$$

where  $A$  is the absorbance,  $b$  the path length of light,  $\epsilon$  the molar absorptivity of the species, and  $I_0$  and  $I$  the intensities of the incident and transmitted light, respectively. When employing this technique with photometric sensors, the medium supporting the selective chemistry, and indeed the selective chemistry itself, should be optically transparent. The reagent and the supporting medium together are commonly referred to as the chemical transducer.

### Reflectance

When the chemical transduction medium used in a photometric sensor is opaque or when it transmits light only weakly, then measurements of the reflected light may be used. Reflection takes place when light infringes on a boundary surface, and two distinct types of reflection are possible. The first is the 'specular' (or mirror type) reflection, which occurs at the interface of a medium with no transmission

through it. The second type is the 'diffuse' reflection, where the light penetrates the medium and subsequently reappears at the surface after partial absorption and multiple scattering within the medium. Specular reflection can be minimized or eliminated through proper sample preparation and optical engineering.

The optical measurements of diffuse reflectance are dependent on the composition of the system. Several theoretical models have been proposed for diffuse reflectance, which are based on the radiative transfer theory, and all models consider that the incident light is scattered by particles within the medium. The most widely used theory in photometric sensors is the Kubelka–Munk theory, in which it is assumed that the scattering layer is infinitively thick, which may, in practice, be the case with the chemical transducers utilized in photometric sensors. The absolute value of the reflectance  $R$  is related to the absorption coefficient  $K$  and the scattering coefficient  $S$  by the equation

$$F(R) = \frac{(1 - R)^2}{2R} = \frac{K}{S} \quad [2]$$

where  $F(R)$  is known as the Kubelka–Munk function.  $K$  can be expressed in terms of the molar absorptivity  $\varepsilon$  and the concentration  $C$  of the absorbing species, as  $K = \varepsilon C$ . The above equation then becomes

$$F(R) = \frac{\varepsilon C}{S} = kC \quad [3]$$

where  $S$  is assumed to be independent of concentration. Equation [3] is analogous to the Beer–Lambert relationship (eqn [1]) and holds true within a range of concentrations for solid solutions in which the absorber is incorporated with the scattering particles and for systems in which the absorber is adsorbed on the surface of a scattering particle. The reflectance values ( $R$ ) are generally evaluated relative to the reflectance of standard reference materials such as barium sulfate.

Alternative theoretical models for reflectance have been formulated which are found to be valid for other types of systems. For example, the Pitts–Giovannelli theory is valid for scattering particles suspended in an absorbing aqueous medium, while the Rozenberg theory is applicable to mixtures of absorbing and nonabsorbing powders.

### Scattering

Unlike the processes of absorption and luminescence emission, scattering of light need not involve an electronic transition between quantized energy levels in atoms or molecules. Instead, a randomization in the

direction of light radiation occurs. Particles that are small when compared to the wavelength of optical radiation give rise to Rayleigh scattering, which is exhibited by all atoms and molecules. If the particles are larger than the wavelength of optical radiation, the scattering of light is called Mie scattering, in which the intensity of scattered radiation can be related to the concentration of the scattering particles.

In both Rayleigh and Mie scattering, the polarization of the particle remains constant. However, with molecules, the incident radiation can promote vibrational changes, which can alter the polarization of the molecule. The frequency of the light scattered by these molecules will be different from that of the incident light, and with much weaker intensity. Such a scattering phenomenon is known as Raman scattering, which can be observed if intense light sources (e.g., lasers) are used, and have also been used in photometric sensor development; discussion of this phenomenon is beyond the scope of this article.

### Evanescent Wave

When light is transmitted through an optical fiber or a waveguide by total internal reflection, a small portion of the light extends out of the central guide, which is referred to as the evanescent wave. In an optical fiber, the evanescent wave penetrates the cladding material. The intensity ( $I$ ) of the evanescent wave diminishes exponentially with increasing distance ( $z$ ) from the interface according to the equation

$$I = I_0 e^{-z/d_p} \quad [4]$$

where  $I_0$  is the electric field intensity at the interface and  $d_p$ , the depth of penetration, is the distance from the interface at which point the electric field intensity has diminished to  $1/e$  of its value at the interface. This characteristic depth of penetration is given by the formula

$$d_p = \frac{\lambda_0}{2\pi \sqrt{(n_1^2 \sin^2 \theta - n_2^2)}} \quad [5]$$

where  $\lambda_0$  is the wavelength of the propagating light,  $n_1$  and  $n_2$  are the refractive indices of the optically dense core and the surrounding medium, respectively, and  $\theta$  is the acceptance cone half-angle of the light entering the core. The distance  $d_p$  is typically of the order of a fraction of a wavelength but increases to infinity as  $\theta$  approaches the critical angle.

The existence of an evanescent wave is important for optical sensors, because devices in which the cladding material of an optical fiber has been removed and replaced by a thin layer of the reagent phase can be fabricated. Here, the optical properties

of the reagent phase can be monitored by means of the evanescent wave and the interaction between the analyte and reagent establishes a rapid equilibrium resulting in a fast response. It is also possible to couple light from one optical fiber to another using the evanescent wave by bringing the cores of the two fibers closer together than the penetration depth of the evanescent field. Consequently optical information can pass from one fiber to another. Surface plasmon resonance (SPR)-based sensors that utilize evanescent wave interaction of light with a metallic layer, usually silver, may also be considered as photometric sensors.

## Chemical Transduction

In photometric sensors, the chemical transducer usually consists of an immobilized reagent (or a reagent phase) which changes its optical property in the presence of an analyte. Reagents for a particular sensing application are often chosen from the analogous solution chemistry. A reagent phase in a photometric sensor may well be a solution of reagent itself whose optical property is monitored by conventional photometry. But for a reusable sensor, the reagent needs to be immobilized on to an inert and stable solid support, e.g., glass, silica gel, organic polymers, etc., by employing physical or chemical procedures. Physical methods of immobilization, which are simple and economical to carry out, include (1) entrapment, in which the reagent is immobilized within the interstitial spaces of a polymeric lattice; (2) surface adsorption, which involves a weak attraction (Van der Waals force or hydrogen bond) between the reagent molecules and the surface of the solid support; and (3) electrostatic attraction, which involves the formation of ion pairs between the charged reagent and the ionic centers of the solid support. Chemical immobilization method is based on the formation of a covalent bond between the reagent molecule and an activated or functionalized form of the polymeric solid support. This method produces the most firmly bound reagent, but several chemical reaction steps are usually required in the synthesis of a bondable reagent phase.

Like any other type of sensor, the ideal photometric chemical sensor should not perturb the sample. In practice, this requires that the amount of analyte present to react with the indicator reagent should be small compared to the total amount of analyte in the sample. If this requirement is not met, then the contact of analyte with the reagent in the chemical transducer will result in a change in the analyte concentration in the sample. This, in turn, will result in a

slow response of the sensor, in addition to the perturbation in the sample. The slow response arises due to the fact that the time required for sufficient analyte to diffuse and to come into contact with the indicator reagent, may be quite long. Such problems are likely to occur with (1) small sample concentration or mass, or (2) sensors with large indicator reagent concentration or mass.

## Transducer Chemistry

Some analyte chemical species are themselves capable of exhibiting optical changes related to their concentrations, which can be measured photometrically using optical fibers. Such sensors, in which separate chemical transduction systems will not be required, are commonly referred to as 'plain-fiber' sensors. Since many analytes do not themselves possess suitable optical characteristics, they may be sensed indirectly through their interaction with an appropriate chemical transduction system. The sensor response function in such chemical transducer-based optical sensors depends on the manner in which the analyte interacts with the reagent phase. For example, in a simple system where a reagent R reacts with an analyte species A forming a product AR can be represented by the reaction

where either R or AR exhibits measurable optical characteristics. The reagent R is usually selective for the particular analyte being sensed. The chemical transduction depends on the equilibrium of the above reaction, and can additionally be described by the following equation

$$K = \frac{[AR]}{[A][R]} \quad [6]$$

where  $K$  is the equilibrium constant of the transduction reaction; the square brackets indicate equilibrium concentration of the species involved.

During the chemical reaction, the reagent R can be consumed so that the measured optical signal due to it can be decreased, or the product AR can be formed when the optical signal would increase due to its formation. In either case, the change in the optical signal measured can be related to the concentration of the analyte A, which causes this change. If  $C_r$  is the total initial concentration of the reagent, then at any time during the reaction

$$C_r = [R] + [AR] \quad [7]$$

Thus, from eqns [6] and [7], the concentration of A can be related to that of R or AR by the following

equations:

$$[A] = \frac{1}{K} \left( \frac{C_r}{[R]} - 1 \right) \quad [8]$$

$$\frac{1}{[A]} = K \left( \frac{C_r}{[AR]} - 1 \right) \quad [9]$$

These equations illustrate that the reaction [I] is a reversible type, which provides sensing with a direct indicator and requires an appropriate equilibrium constant for the desired range of analyte concentration. The sensor response also depends on  $C_r$ . Furthermore, any uncontrolled variable that affects  $K$  will be a source of interference in the measurement, for example, ionic strength of the medium or temperature.

The most prominent example of the use of direct indicators can be found in optical pH sensors. Because of the multitude of pH indicators (also called acid–base indicators) available with different  $K$  values, it would not be difficult to find a pH indicator to cover virtually any desired pH range. Metal ion sensors based on direct indicators have been studied but they tend to be limited by the fact, in many cases, that the equilibrium constant depends on pH. Sensors for ammonia and carbon dioxide also involve the use of direct indicators. The chemical transducers in these sensor systems consist of suitable buffer and pH indicator enveloped by a gas permeable membrane.

If the measured optical parameter is dependent on the concentration ratio  $[AR]/[R]$ , then the sensor response is no longer dependent on  $C_r$ , but dependent on  $K$ . Thus

$$[A] = \frac{1}{K} \left( \frac{[AR]}{[R]} \right) \quad [10]$$

In general, in photometric sensors, reversible reactions are preferred in the chemical transduction systems because they can provide continuous and unperturbed measurements. The response time (i.e., the time to reach the equilibrium) is dependent on mass transfer. Reversible interactions of analytes with reagents, which do not involve chemical reactions, such as the dynamic fluorescence quenching by oxygen, can provide sensors with short response times. This is because of the fact that the fluorescence quenching effect takes place via the transfer of energy from the reagent to the analyte molecules through contact, and there is no consumption of analyte or reagent during this process.

Nonreversible chemical reactions may be employed in the photometric transduction systems, which can result in ‘one shot’ type sensor devices. Though there will only be a limited merit in utilizing

such reactions in sensors, they can provide high sensitivity for measurements. The reagent phases in these sensors can be formulated as flat strips or slides, so that high reproducibility in measurements may be achieved from sensor to sensor. In many cases, the reagents can be regenerated by the use of another chemical reaction and reused for further measurements. For example, the sensor for lead based on immobilized dithizone can be reversed using hydrochloric acid solutions.

Indirect chemical reactions involving two or more reagents and/or reactions can be used as optical chemical transducers. For example, consider the following reactions:

where  $X$  is the analyte,  $M$  the immobilized reagent, and  $S$  the species which competes with  $X$  for  $M$ . In the sensor, the optical property of free  $S$  is measured. In the absence of  $X$ , the reaction [II] will proceed to the right and the optical signal measured will be reduced due to increasing amount of  $S$  being bound to  $M$ . However, as the concentration of  $X$  in the sample increases, the reaction [III] will proceed to the right and that in reaction [II] to the left, thus resulting in free  $S$ . The optical signal measured due to free  $S$  will then be proportional to the concentration of  $X$ . This concept has been employed in the development of a glucose sensor. In this system,  $X$  was glucose,  $S$  was fluorescein-labeled dextran, and  $M$  was immobilized concanavalin A, a carbohydrate binding protein. The sensor response to glucose was detected by the measurement of the fluorescence of fluorescein-labeled dextran released in the optical path. In general, the use of indirect indicators in optical transducers offer the potential of varying the effective equilibrium constant which, in turn, determines the range of concentrations of analyte to which the sensor responds; this is not possible with direct indicators.

Additionally, phenomena such as catalysis, ion-pair interactions, chemi- or bioluminescence, redox changes, etc., may be employed in the chemical transduction process. In catalysis type of system, for example, the immobilized reagent catalyzes the conversion of analyte to form a product whose optical property is then measured. Several examples of such reactions include those which utilize immobilized enzymes acting as a catalyst. The response of the sensor in such a system, involves a steady state, in which the rate of product formation is equal to the rate at which it is removed from the transducer by processes such as diffusion and convection. The concentration of the steady-state product increases with

that of the analyte. Thus, this type of transduction system responds continuously but, with respect to mass transfer, controlled reaction conditions will be required.

### Transducer Design

A variety of transducer configurations that has been employed in photometric sensor devices fall into two sensor types: extrinsic sensors and intrinsic sensors. While in the former sensor type the optical fiber merely acts as a light guide, conveying the optical information between the optical source and the chemical transducer and between the chemical transducer and the detector, in the latter sensor type the optical fiber, probably in some modified form, would become a part of the transducer.

One of the critical elements in the design of a photometric sensor is the configuration of the sensing terminus. Its configuration often determines detectability, linear dynamic range, rate of response, the effects of interferences, site specificity, and useful lifetime of the sensor. Most important design considerations include (1) the method of immobilization and (2) the shape and size of the terminus and the amount of reagent phase.

According to the working principle, both extrinsic and intrinsic sensor types can be differentiated by their sensing schemes. As mentioned earlier, optical fibers have been employed in photometric sensors either as plain-fiber sensors or transducer-based sensors. In the former, the analyte species possesses some measurable optical property, which is measured and related to its concentration. The transducer-based optical sensor is the most common type of the two. The interaction between the light and the analyte/reagent system takes place at one region of the optical fiber and a variety of sensor configurations can be grouped into (1) transmissive configuration, in which the interaction occurs along the length of the fiber, and (2) nontransmissive configuration, where the interaction takes place at a distal end of the optical fiber system.

Some of the sensor configurations studied to date and commonly employed in both extrinsic and intrinsic types of photometric sensors are shown in **Figures 1A–1J**. Light is launched at one end of the optical fiber and is detected at the other end in the transmissive type of configuration with the liquid or gaseous analyte passing through a flow-cell (**Figure 1A**) or a gap (**Figure 1B**) interposed along the optical fiber, or with the analyte surrounding the cladding-removed fiber in a flow-cell (**Figure 1C**). On the other hand, the cladding of the optical fiber may be replaced with a chemical transducer (**Figure 1D**) whose

change in the optical property is measured as a function of the analyte concentration. In those cases where cladding-removed optical fibers are employed (**Figures 1C** and **1D**), optical signals are measured through the evanescent wave interaction of the light with the analyte or the reagent material.

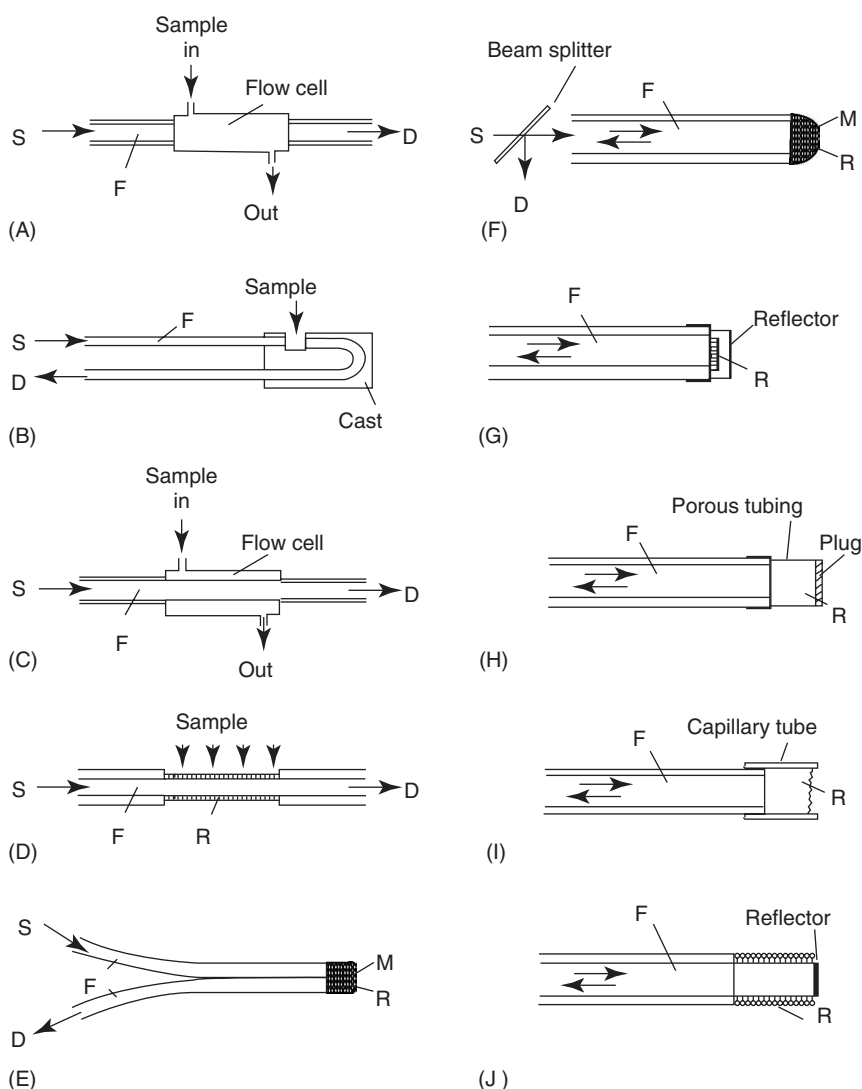

The nontransmissive type of configuration employed in photometric sensors are depicted in **Figures 1E–1J**, in which the incident light and the detected light are transmitted along the same or different optical fibers, and the sample system is encountered at a terminus of the optical fiber system. When single optical fibers are used in sensors (**Figures 1F–1J**), the light, supplied and collected by the same fiber, is discriminated either temporally or by wavelength with the aid of a beam splitter. However, in a bifurcated optical fiber system (**Figure 1E**), the incident and detected light travel along different fibers, and such a system can be fabricated using two optical fibers or an optical fiber bundle. In the latter, the light supply fibers and the detecting fibers are randomly distributed at the terminus of the fiber system. In general, sensors based on the use of single optical fibers are simpler to construct and the single fiber systems exhibit a greater field of view compared with the bifurcated optical fiber system, which also involves a blind volume in the field (**Figure 2**).

The reagent phases in chemical transducer-based sensors are normally fabricated by using physical or chemical methods, as described earlier in this article, and these are interfaced appropriately with optical fibers in order to produce an optimal sensor design with respect to a particular type of application. In these sensors aside from the chemical transduction process that recognizes the analyte interaction, the optical signals transmitted to the detector also need to be transduced further into a measurable electrical signal that can be displayed, usually, by a meter.

### Instrumentation

The basic instrumentation associated with photometric sensors is simple and requires both optical and electrical components. Apart from the optical fiber, the instrumentation system involves a light source, photodetector and associated display, optical components such as lenses, couplers and connectors, and monochromators or filters for wavelength selection. A typical instrumentation system employed in conjunction with photometric sensors is shown schematically in **Figure 3**.

The light source must be able to provide a stable and intense optical radiation. Several types of sources have been employed in photometric sensors, namely incandescent lamps, gas lasers, LEDs, and laser

**Figure 1** Transducer designs (see text for details). S, source; D, detector; F, optical fiber; R, reagent phase; M, membrane.

diodes. Incandescent sources, such as tungsten lamps and quartz-halogen lamps, emit a broad spectrum of optical radiation and are used as sources of ultraviolet and visible light in short-range optical sensors. Gas lasers are useful as general-purpose sources of highly intense and coherent radiation and are employed in long-distance or remote sensing systems. LEDs and laser diodes are miniature sources of high-intensity monochromatic radiation. LEDs produce incoherent light with a typical spectral bandwidth of 40–50 nm and are useful in short range sensing up to a distance of 1 km. Laser diodes, on the other hand, radiate a coherent beam of light with a narrower spectral bandwidth of the order of 5–10 nm or less and are excellent sources for remote sensing systems.

The detection utilized in the instrumentation is essentially a photon-counting device in which optical signals are converted into electrical signals which can

be easily amplified electronically. It is essential that the photodetector has peak sensitivity at the measurement wavelength, generate a minimal amount of noise with respect to the transmitted signal, and respond rapidly to variations in the intensity of light reaching it. Various types of photodetectors have been used in optical sensors including photomultiplier tubes, PIN photodiodes, photodiode arrays, and avalanche photodiodes.

In optical sensing system, it is necessary to employ optical couplers and lenses in order to focus the light beam to the optical fiber and direct radiation from the return fiber to the photodetector. Injecting light from a source into a fiber is a more tedious operation. Laser sources produce a coherent beam of light with a cross-section almost equal to the cross-sectional area of the optical fiber, and, therefore, can be coupled very efficiently to the fiber. On the

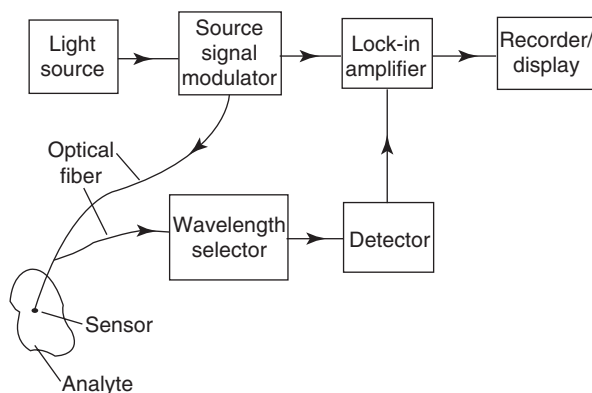

**Figure 2** Field of view with (A) bifurcated (or twin) optical fibers and (B) single optical fiber. S, source; D, detector; F, optical fiber.

other hand, incandescent lamps and LEDs radiate divergent light, which need to be focused using lenses in order to launch the light into the optical fiber.

The coupling of the photodetector to the optical fiber system is more easily accomplished due to the fact that the detectors have relatively large active surface areas and large acceptance angles. However, it will be necessary that wavelengths other than that of the analytical signal have to be excluded from the light that is reaching the detector. Such optical resolution needs to be carried out if broadband sources, e.g., incandescent lamps, are used in the optical system. Isolation of desired wavelengths is usually accomplished by the use of filters or monochromators. Simple optical filters attenuate significant amount of light and, thus, could lower the sensitivity of the system. Monochromators offer high efficiency of light throughput and can be adapted for different wavelengths.

Extraneous optical radiation can be excluded from reaching the detector by suitable modulation of the light source and by synchronizing the detector to this modulation frequency. Any instrumental drifts caused by the electronic components of the system, such as aging of the light source, fluctuations in the power supply, fouling, etc., may be eliminated by

## Introduction

Piezoelectric resonators are sensor devices that respond to changes in temperature, pressure, and, most importantly, to changes in the physical properties of

**Figure 2** Field of view with (A) bifurcated (or twin) optical fibers and (B) single optical fiber. S, source; D, detector; F, optical fiber.

other hand, incandescent lamps and LEDs radiate divergent light, which need to be focused using lenses in order to launch the light into the optical fiber.

The coupling of the photodetector to the optical fiber system is more easily accomplished due to the fact that the detectors have relatively large active surface areas and large acceptance angles. However, it will be necessary that wavelengths other than that of the analytical signal have to be excluded from the light that is reaching the detector. Such optical resolution needs to be carried out if broadband sources, e.g., incandescent lamps, are used in the optical system. Isolation of desired wavelengths is usually accomplished by the use of filters or monochromators. Simple optical filters attenuate significant amount of light and, thus, could lower the sensitivity of the system. Monochromators offer high efficiency of light throughput and can be adapted for different wavelengths.

Extraneous optical radiation can be excluded from reaching the detector by suitable modulation of the light source and by synchronizing the detector to this modulation frequency. Any instrumental drifts caused by the electronic components of the system, such as aging of the light source, fluctuations in the power supply, fouling, etc., may be eliminated by

the device surface's contacting materials. These physical properties include variations in interfacial mass density, layer thickness, viscosity, and viscoelasticity. The very sensitive and selective responses of the piezoelectric devices obtained by coating their surfaces with chemically or biologically selective films have been exploited by many researchers working in the field of analytical applications. This article will describe the basic principles behind piezoelectric resonators (Figure 1) and will review their major sensory application areas.

## Principles of Piezoelectric Sensors

### Piezoelectricity

Piezoelectricity (*piezin*, Greek, to press) was first described in 1880 by Pierre and Jacques Curie, who showed that upon mechanical deformation (torsion, pressure, bending, etc.) of a solid material along an appropriate direction, electrical charges occur on the material's opposing surfaces. Conversely, applying an external electric field to a material induces a mechanical deformation. This phenomenon is called the converse piezoelectric effect. Piezoelectricity can only occur in crystals with an inversion center and from a crystallographic viewpoint, 21 point groups fulfill

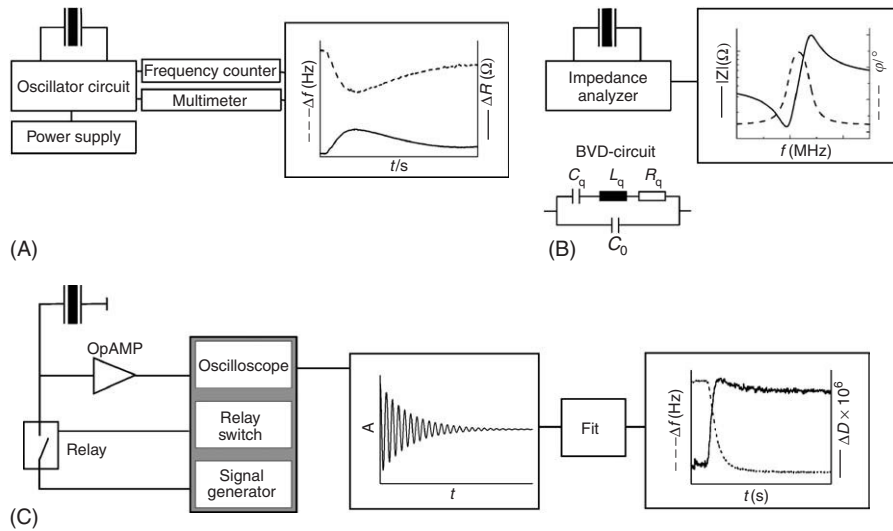

this requirement. However, only 20 point groups do have a nonzero piezoelectric constant. There are a large number of crystals commonly used as piezoelectric materials such as Rochelle salt, sodium chlorate, tourmaline, or quartz. Among them,  $\alpha$ -quartz ( $\text{SiO}_2$ ) is very unique, as it combines mechanical, electrical, chemical, and thermal properties, which has led to its commercial significance. The quartz crystal may provide a large variety of different resonator types depending on the cut-angle with respect to the crystal lattice. The cut-angle determines the mode of induced mechanical vibration. Resonators operating in thickness shear mode (TSM), face shear mode, or flexural mode can be obtained from the mother crystal with eigenfrequencies ranging from  $5 \times 10^2$  Hz to  $3 \times 10^8$  Hz.

### Thickness Shear Mode Sensors

For TSM resonators, which are also known as bulk acoustic wave sensors, AT-cut crystals are used that are prepared by slicing a quartz wafer at an angle of  $35.25^\circ$  to the optical  $z$ -axis. AT-cut quartz crystals are superior because they exhibit a tremendous frequency stability of  $\Delta f/f \approx 10^{-8}$  with a zero temperature coefficient between 0 and  $50^\circ\text{C}$ . Owing to the converse piezoelectric effect, the crystal plate can be excited to mechanical oscillation by applying an alternating potential difference via metal electrodes (commonly disk-like gold or silver electrodes) that are deposited on each side of the quartz plate. Shear waves of opposite polarity are generated at the electrodes on either side of the crystal with the shear displacement in plane with the crystal surface. Both waves traverse across the thickness of the quartz plate, are reflected at the opposing crystal face (phase shift  $\pi$ ), and then return to their origin. Constructive interference of incident and return waves occurs when the acoustic wavelength is an odd multiple of twice the crystal thickness ( $2d_q$ ) and standing wave conditions are then established. Particle displacement of the standing acoustic wave is maximal at the crystals' surfaces and a displacement node exists in the center of the resonator. Thus, the eigenfrequency of the TSM resonator is inversely proportional to its thickness  $d_q$  ( $f = nv_p/2d_q$ , where  $v_p$  is the phase velocity). For instance, a TSM resonator with a thickness of  $330 \mu\text{m}$  exhibits a resonance fundamental frequency  $f_0$  of 5 MHz with odd overtones  $n$  (15 MHz, 25 MHz, etc.). The lateral dimensions of the quartz plate depend on the mother crystal and are usually 10–25 mm in diameter.

### Detection principles

*Active oscillator mode* Stable oscillations of a quartz plate only occur at the resonance frequency

**Figure 2** Setups used for TSM resonators: (A) active mode, (B) impedance analysis of the oscillation (passive mode), and (C) ring down method (QCM-D<sup>TM</sup>).

of the crystal. If the crystal is incorporated into a feedback loop of an oscillator circuit, it becomes the frequency-determining element as its  $Q$ -factor is very large (20 000–50 000 for 10 MHz fundamental frequency in air). The frequency of the quartz plate can be read out by a frequency counter. Using an amplitude-controlled oscillator circuit that monitors the amplitude apart from the resonance frequency, damping of the quartz oscillation can also be recorded (Figure 2A). Self-sustaining oscillation of TSM resonators is, however, restricted to load situations with the phase maximum above zero.

**Passive oscillator mode** Impedance analysis of the forced oscillation of the quartz plate provides valuable information about the coating even if the active mode is not applicable anymore. For impedance analysis, a frequency generator is used to excite the crystal to a constraint vibration near resonance while monitoring the complex electrical impedance and admittance, respectively, dependent on the applied frequency (Figure 2B). For low load situations near resonance, an equivalent circuit with lumped elements – the so-called Butterworth–van-Dyke (BVD) circuit – can be applied to model the impedance data. The BVD circuit combines a parallel and series (motional branch) resonance circuit. The motional branch consists of an inductance  $L_q$ , a capacitance  $C_q$ , and a resistance  $R_q$ . An additional parallel capacitance  $C_0$  arises primarily from the presence of the dielectric quartz material between the two surface electrodes (parallel plate capacitor) also containing parasitic contributions of the wiring and the crystal holder (Figure 2B).

**QCM-D<sup>TM</sup> technique** Kasemo and co-workers have developed an interesting technique that measures the resonance frequency  $f$  and the dissipation factor  $D$ , which is the inverse of the  $Q$ -factor, of the oscillation simultaneously by a ring down method. The quartz plate is excited every second with a frequency generator followed by switching off the source and recording the free decay of the quartz oscillation. The dissipation factor and resonance frequency are obtained from each cycle by a curve fit of an exponentially damped harmonic oscillator function (Figure 2C).

**Mass sensitivity in the gas phase and in vacuum** The resonance frequency of an AT-cut quartz plate operating in shear mode is altered by adding mass to the surface of the crystal since this increases the thickness of the quartz plate. In 1959, Sauerbrey provided a mathematical treatment of the mass sensitivity of the quartz oscillation, which led to the term quartz crystal microbalance (QCM). He showed that a thin, rigid, and uniform film deposited on the electrode's surface results in a frequency decrease  $\Delta f$  that is proportional to the deposited mass  $\Delta m$  if the resonator is operated in the gas phase or in vacuum. Changes in the motional resistance ( $\Delta R$ ), i.e., damping, is zero. If the density of the mass layer is equal to that of the quartz crystal, the following relation applies:

$$\Delta f = -\frac{2nf_0^2}{A\sqrt{\mu_q\rho_q}}\Delta m = -S_f\Delta m \quad [1]$$

where  $A$  is the piezoelectric active electrode area (typically ranging between 0.2 and 0.4 cm<sup>2</sup>),

$\mu_q$  the piezoelectric stiffened shear modulus ( $2.96 \times 10^{10} \text{ N m}^{-2}$ ), and  $\rho_q$  the density of quartz ( $2.65 \text{ g cm}^{-3}$ ). The integral mass sensitivity  $S_i$ , also known as Sauerbrey constant, depends on the square of the fundamental frequency  $f_0$  and increases proportionally to the overtone number  $n$ . The sensitivity  $c_m^{\text{TSM}}$  of the TSM is defined as

$$c_m^{\text{TSM}} = \lim_{\Delta m/A \rightarrow 0} \frac{A}{\Delta m} \left( \frac{\Delta f}{f_0} \right) \approx - \frac{2f_0}{\sqrt{\mu_q \rho_q}} \quad [2]$$

A more detailed theoretical treatment of the propagating acoustic wave that solves the general wave equation of motion for the proper boundary conditions reveals that the shear amplitude along the crystal surface is not uniform but radially symmetric. This, in turn, means that the quartz resonator is not uniformly sensitive to the adsorption of a rigid foreign material. The amplitude is maximal in the center of a disk-like electrode and decreases monotonically with increasing distance from the center vanishing at the electrode edges. Empirically, the radial mass sensitivity can be described by a Gaussian function with its maximum sensitivity in the center of the electrode.

If the mass deposited on the electrodes is not rigid and measurements are performed in liquid phase, the TSM resonator does not behave like a simple mass sensor anymore, but provides valuable information about the viscous and viscoelastic properties of the deposited material. Many of the applications of the QCM, in which polymer films, biomolecules, or even whole cells are investigated, benefit from this additional information. In all these cases, the Sauerbrey equation does not apply strictly, and it might become impossible to extract corresponding mass binding quantities from merely recording changes in resonance frequency.

**Liquid loading** Most QCM applications require the sensor to work in a liquid environment. The coupling of the crystal surface to the liquid dramatically alters its resonance frequency as the shear motion of the surface generates motion in the liquid near the interface. Thus, a fraction of the kinetic energy of the oscillation is radiated into the bulk phase and is thereby dissipated. The frequency change upon contact of the resonator surface with a Newtonian liquid was first analytically described by Kanazawa and Gordon in 1985:

$$\Delta f = -f_0^{\frac{3}{2}} \sqrt{\frac{\eta_L \rho_L}{\pi \mu_q \rho_q}} \quad [3]$$

where  $\eta_L$  is the viscosity and  $\rho_L$  the density of the liquid. The characteristic decay length  $\delta$  of the shear wave within the bulk phase depends on the density

and viscosity of the liquid and is  $\sim 250 \text{ nm}$  (5 MHz TSM resonator) in water at  $20^\circ\text{C}$ .  $\Delta R$  can be expressed according to the acoustic load concept:

$$\Delta R = \frac{f_0^{3/2} L_q}{\sqrt{\mu_q \rho_q}} \sqrt{\eta_L \rho_L} \quad [4]$$

When using TSM resonators in liquids and in particular in aqueous solutions, other external parameters – besides the viscous load – affect the shear oscillation. These include the generation of longitudinal (compressional) waves, which are reflected at the liquid–air interface and alter the resonance frequency of the quartz plate. If working in an open crystal holder, periodical changes in the resonance frequency are recorded due to evaporation of the liquid. Other important parameters that influence the resonance frequency of the quartz crystal in solution are the ionic strength and dielectric constant of the electrolyte. If the QCM operator has to change the buffer conditions, an undesired parasitic frequency shift may occur, depending on the shape of the electrodes and conductance of the solution. Surface roughness of the quartz resonator also influences interpretation of adsorption phenomena. Alteration of hydrophilicity upon adsorption can lead to tremendous changes in resonance frequency since rough and hydrophilic surfaces entrap liquids in small cavities thus contributing to the overall mass detected by the device, while hydrophobic cavities are not wetted by the liquid resulting in the inclusion of air or vacuum. This implies that the resonance frequency shifts to smaller values when changing from a hydrophobic to a hydrophilic surface. When working in buffer solutions, the influence of the electrochemical double layer on the resonance frequency should also be taken into account. Considering the electrochemical double layer as a rigid mass with an extension of a few nanometers in the  $z$ -direction leads to an additional frequency change.

**Viscoelastic loading** The impact of viscoelastic materials on the electromechanical properties of a TSM resonator can be best described by the acoustic load concept. Adding a viscoelastic film with a sufficiently small shear modulus to the quartz crystal results in an additional frequency shift as expected for a thin rigid layer if the environment is air, or a decrease in frequency shift as expected from eqn [1] if the layer is adsorbed in liquid. The so-called ‘extra mass’ effect occurring in air can be expressed by a plus sign in eqn [5]:

$$\Delta f \propto 2\pi f_0 \rho_F h_F \left( 1 + \frac{1}{3} \frac{G'}{\rho_F |G|^2} (2\pi f_0 \rho_F h_F)^2 \right) \quad [5]$$

The increased shift in frequency by a thin viscoelastic film may increase the frequency response to added mass as compared to eqn [1], thus acting as an acoustic amplifier. The change in motional resistance upon addition of a film with a thickness  $h_F$ , a density  $\rho_F$ , and a complex shear modulus  $G = G' + iG''$  can be estimated as

$$\Delta R \propto 2\pi f_0 \rho_F h_F \left( \frac{1}{3} \frac{G''}{\rho_F |G|^2} (2\pi f_0 \rho_F h_F)^2 \right) \quad [6]$$

where  $G'$  is the storage modulus and  $G''$  the loss modulus. The change in resonance frequency is decreased if a soft film is deposited in a liquid environment referred to as the ‘missing mass’ effect as is obvious from the minus sign in eqn [7]:

$$\Delta f \propto 2\pi f_0 \rho_F h_F \left( 1 - \frac{2\pi f_0 \rho_L \eta_L}{\rho_F} \frac{G''}{|G|^2} \right) \quad [7]$$

while  $\Delta R$  reads:

$$\Delta R \propto 2\pi f_0 \rho_F h_F \left( \frac{2\pi f_0 \rho_L \eta_L}{\rho_F} \frac{G'}{|G|^2} \right) \quad [8]$$

### Surface Acoustic Wave Sensors

Surface acoustic wave (SAW) devices are characterized by SAWs electrically excited in a piezoelectric single crystal plate such as quartz or lithium niobate. Surface waves travel along the surface of a relatively thick solid material penetrating to a depth of one wavelength. The stress-free boundary of a solid gives rise to surface confined waves propagating as coupled longitudinal and transversal waves. The frequencies of SAW sensors are usually between 50 MHz and a few GHz. The displacement components decay exponentially within the solid. The surface acts as an acoustic waveguide. SAWs can be excited and detected by patterned interdigital transducers (IDT) on the surface of the piezoelectric crystals. Each ‘finger’ is the origin of a SAW. The transducer works most efficiently if the periodicity matches the wavelength of the surface wave occurring at  $f = v_p/d$ , in which  $v_p$  denotes the propagation velocity and  $d$  the distance between the interdigital fingers of one electrode, i.e., the periodicity. Generally, resonators can be distinguished as two-port delay lines and one-port resonators. Two-port delay lines work with one IDT as a transmitter and one as a receiver creating resonant traveling waves. One-port resonators consist of one IDT structure in between two reflectors thus producing a standing wave in both directions. The resonance frequencies of a

single-port resonator are given by  $f_n = nv_p/2l$ , in which  $l$  is the distance between the reflectors. The  $Q$ -factor of SAW devices is lower than that of the TSM and ranges between 6000 and 12 000.

**Mass loading** If the deposited mass is a thin rigid film, the kinetic energy of the synchronously vibrating system is increased without energy loss due to viscous damping. This leads to a decrease in propagation velocity, which is the strength of the SAW sensor since it reacts very sensitively to changes in the propagation velocity. The influence on the resonance frequency is given by eqn [9]:

$$\Delta f = f_0 \frac{\Delta v}{v_p} = c_m^{\text{SAW}} f_0 \frac{\Delta m}{A} \quad [9]$$

The mass sensitivity  $c_m^{\text{SAW}}$  (a negative value) increases with the fundamental frequency  $f_0$ , which is considerably higher ( $> 100$  MHz) than that of TSM resonators rendering the sensitivity of a 100 MHz SAW sensor 200 times higher than the mass sensitivity of a 5 MHz quartz crystal.

However, the use of SAW sensors in a liquid environment is not recommended, since the wave is damped by the liquid. Energy loss occurs due to the generation of compressional waves by displacement components parallel to the surface normal and the viscous coupling of displacement components parallel to the surface.

### Love-Wave, Shear-Horizontal SAW and Acoustic Plate Mode Sensors

A Love wave is a propagating shear mode wave supported on semiinfinite substrates with a waveguide layer that exhibits a shear acoustic speed lower than that of the substrate. Other acoustic wave sensors utilizing IDT to generate and detect propagating shear modes are shear horizontal polarized surface acoustic waves (SH-SAWs) and surface transverse waves. Shear horizontal acoustic plate modes (SH-APMs) are propagating modes involving the thickness of a thin piezoelectric plate and the detection and excitation by IDT. The SH-modes in SH-APM resonators can be considered as a superposition of plane waves with in-plane displacement reflected at a particular angle between the upper and lower face of the quartz resonator involving the full thickness of the resonator.

So far, numerical modeling of mass and liquid response was specifically directed to a particular device type. However, recent developments present a unified view of the different types of resonators by employing the dispersion equation approach. In brief, mass sensitivity depends on the point of operation on the

dispersion curve (phase velocity  $v$  as a function of normalized waveguide layer thickness  $z$ ), which is chosen to be the point of steepest slope corresponding to the transition where wave displacement is predominately in the substrate or the waveguide layer. The mass sensitivity of a Love-wave device can be expressed as:

$$c_m^{\text{Love}} = \lim_{\Delta m/A \rightarrow 0} \frac{A}{\Delta m} \left( \frac{\Delta v}{v_0} \right) \approx \frac{(1 - v_p^2/v_0^2)}{(1 - v_l^2/v_0^2)} \frac{f_0}{\sqrt{\mu_l \rho_l}} \left( \frac{d \ln(v)}{dz} \right)_{z=z_0} \quad [10]$$

$v$  is the phase velocity of the composed resonator as a function of  $z$ ,  $v_p$  that of the mass layer, and  $v_l$  the corresponding phase velocity of the waveguide layer.  $v_0$  is the phase velocity of the unperturbed system consisting of the waveguide and substrate at the point of operation  $z_0$  on the dispersion curve.  $\mu_l$  is the Lamé constant and  $\rho_l$  the density of the waveguide layer. The local slope of the  $v(z)$  dispersion curve might itself be frequency depending and as a consequence it would not be correct to claim that the sensitivity is proportional to the frequency at operation.

It was shown that eqn [10] can be employed to describe the sensor response of both SH-SAW and SH-APM resonators all with acoustic waveguides. In conclusion, the slope at the operating point  $z_0$  of the dispersion curve determines the sensitivity of the device.

### Flexural Plate Wave Sensors

Flexural plate wave (FPW) resonators are thin, rectangular membranes made of tension-free silicon nitride embedded in a frame of silicon manufactured photolithographically. Oscillations of these plates, which are only a few micrometers thick, can be excited piezoelectrically via IDT, electrostatically, or by using magnetic transducers. FPW sensors are characterized by a high  $Q$ -factor and low-energy loss in fluids at a low resonance frequency. Although the mechanical amplitude is rather high (100 nm), energy dissipation is low since the phase velocity of the acoustic wave is lower than the velocity of sound in most liquids (900–1500 m s<sup>-1</sup>). Low resonance frequencies (1–10 MHz) permit the use of low-cost electronics providing an attractive alternative to the less sensitive TSM resonators.

The simplest case of an oscillating isotropic plate includes an infinite set of waves known as Lamb waves. Two sets of waves can be distinguished: symmetric waves ( $S_0$ ,  $S_1$ , etc.) with particle displacements symmetric about the neutral plane and antisymmetric waves ( $A_0$ ,  $A_1$ , etc.), whose displacements have odd symmetry. For sufficiently thin plates only two waves occur,  $A_0$  and  $S_0$ . Thinner membranes exhibit

lower phase velocities for the  $A_0$  mode, in which the plate undergoes flexure as the wave propagates, while phase velocity reaches its maximum value for the  $S_0$  mode. In the case of the  $A_0$  mode the eigenfrequency decreases with decreasing thickness of the membrane at a given wavelength  $\lambda$ :

$$f = \frac{1}{\lambda} \frac{\sqrt{B}}{\rho d} \quad [11]$$

$B$  denotes the bending stiffness,  $\rho$  the density, and  $d$  the thickness of the membrane.

**Mass loading** Increasing the mass of the isotropic plate by a thin, rigid foreign mass layer results in a decreased phase velocity of the  $A_0$  Lamb wave:

$$\Delta f = c_m^{\text{FPW}} f_0 \frac{\Delta m}{A} \quad [12]$$

with  $c_m^{\text{FPW}} = -1/\rho d$ , the integral mass sensitivity, which can be increased by using thinner plates thus reducing the phase velocity and as a consequence the resonance frequency.

## Analytical Applications of Piezoelectric Sensors

### Gas-Phase Detection

The first gas-phase sensor based on TSM resonators was described by King in 1964. He used a range of standard chromatographic stationary phases to selectively adsorb vapors. The first analytical application of an SAW sensor was reported in 1979 by Wohltjen and Dessy, who used the device as a detector for gas chromatography, and as a thermo-mechanical polymer analyzer to determine glass transition temperatures and effects of ultraviolet curing on photoresists.

The key feature of all acoustic wave sensors for detecting vapors is that measurable characteristics of the acoustic wave is altered as a result of adsorption on the surface of a receptive layer or absorption into the bulk of a thin layer (Figure 3). After sorption of the vapor by a thin film on top of the acoustic resonator equilibrium conditions are established and as a consequence of the increased mass or more accurately the change in the phase velocity of the acoustic wave a signal is created. Surface coatings generally enhance the sorption of vapors with the key properties of selectivity and sensitivity while affording reversibility. Typically, rubbery polymers were used on SAW devices such as polyisobutylene or substituted polysiloxanes but also self-assembled

shift together with the assumption of a linear relation between frequency shift and mass load allow the determination of binding and rate constants of protein adsorption. Moreover, the QCM method has been evolved as a routine technique to control the quality of multilayers as prepared by the Langmuir–Blodgett technique and self-organization processes. In the early days of the QCM operated in liquids, it was postulated that the adsorbed amount of protein can be calculated from the frequency shift using eqn [1]. However, numerous publications yet established that protein adsorption performed in liquid often leads to larger frequency shifts than in air.

The high specificity of antigen–antibody reactions and the ability to generate antibodies against a variety of biological and nonbiological substances led to the development of a variety of piezoelectric immunosensors. The online detection of antibody–antigen reactions in aqueous solution was first reported by Roederer and Bastiaans on SAW resonators and by Thompson and co-workers on TSM resonators. Nowadays, the spectrum ranges from applications in clinical analysis through the determination of bacteria in food industry to environmental analysis for the detection of organic compounds by using an antigen–antibody reaction. Since the invention of phage libraries immunosensing systems based on the QCM has been successfully applied as a device for the screening of phage libraries and determination of antibody affinity.

A rather new and very exciting application of TSM resonators is the detection and characterization of pro- and eukaryotic cells, as the technique provides information of the viscous and viscoelastic load on the surface. Most piezosensors used for the detection of bacteria in solution are based on an antigen–antibody reaction, in which the bacterium binds to the corresponding surface confined antibody and thus can be monitored. In most cases, a linear relation between the bacterial cell number and frequency shift is found enabling one to calibrate the system for the bacterial cell numbers. However, whole cells do not always form complete layers on the surface; they have dimensions extending that of the acoustic

damping region in liquids and a viscoelasticity differing from simple Newtonian behavior. To obtain a set of data allowing one to extract cell-specific parameters impedance analysis in the range of the resonance frequencies of the quartz plate is hence required.

Nowadays, the spectrum ranges from applications in clinical analysis through the determination of bacteria in food industry to environmental analysis for the detection of organic compounds by using an antigen–antibody reaction. Since the invention of phage libraries immunosensing systems based on the QCM has been successfully applied as a device for the screening of phage libraries and determination of antibody affinity.

A rather new and very exciting application of TSM resonators is the detection and characterization of pro- and eukaryotic cells, as the technique provides information of the viscous and viscoelastic load on the surface. Most piezosensors used for the detection of bacteria in solution are based on an antigen–antibody reaction, in which the bacterium binds to the corresponding surface confined antibody and thus can be monitored. In most cases, a linear relation between the bacterial cell number and frequency shift is found enabling one to calibrate the system for the bacterial cell numbers. However, whole cells do not always form complete layers on the surface; they have dimensions extending that of the acoustic

damping region in liquids and a viscoelasticity differing from simple Newtonian behavior. To obtain a set of data allowing one to extract cell-specific parameters impedance analysis in the range of the resonance frequencies of the quartz plate is hence required.

## Tissue-Based

**S B Adeloju**, Monash University, Gippsland, VIC, Australia

## Introduction

The use of plant and animal tissues, instead of isolated enzymes, for the construction of biosensors has attracted much interest in the last three decades.

Several biological materials, such as animal tissues, bacterial cells, and plant tissues, have been used for this purpose. In earlier studies, animal materials, such as heart, liver, and kidney, were used exclusively for the construction of biosensors. However, since the introduction of the first plant-tissue-based electrochemical biosensor by Kuriyama and Rechnitz in 1981, the use of plant tissues has attracted the most interest for the development of tissue-based biosensors. The popularity of the use of plant tissues as natural enzyme sources for the construction of biosensors was further enhanced by the introduction of a banana tissue biosensor, known as the 'bananat-rode', in 1985. Since then several other plant tissues, such as fruits, leaves, roots, seeds, and vegetables, as listed in **Table 1**, have been used for the development of a wide range of tissue-based biosensors.

Plant leaves have attracted considerable interest in the development of tissue-based biosensors because of their unique natural structural arrangement. The

waxy eternal coating (cuticle) is hydrophobic in nature, but permits active gas exchange through the stomata openings. For this reason, leaves are excellent choice of material for development of tissue-based biosensors that employ potentiometric gas sensing electrodes, such as carbon dioxide electrode and ammonia gas sensing membrane electrode. One such example is the use of cucumber leaves attached to an ammonia gas sensing membrane electrode for tissue-based biosensing of cysteine. In this case, the substrate (cysteine) diffused into the spongy layer of the leaf where it gets broken down into products, which include ammonia that was readily detected by the ammonia electrode. There are several other examples of the use of plant leaves for the development of other biosensors, some of which are also listed in **Table 1** and others will be discussed later.

Other popular plant tissue materials of choice include several different fruits and vegetables. The considerable interest in these plant tissue materials is

**Table 1** Some of the reported plant-tissue-based biosensors

<i>Substrate/analyte</i>	<i>Plant tissue</i>	<i>Enzyme</i>	<i>Electrode/element</i>
Alcohol	Mushroom	Alcohol oxidase	Oxygen electrode
	Tomato seeds	Alcohol dehydrogenase	Carbon paste electrode
Amino acids	Parsley seeds	Amino acid oxidase	Ammonia gas sensor
Ascorbic acid	Cabbage, cucumber, yellow squash	Ascorbic acid oxidase (AAO)	Oxygen electrode/carbon paste electrode
Atrazine	Potato	Polyphenol oxidase (PPO)	Oxygen electrode
Catechol	Coconut, potato	PPO	Glassy carbon or O <sub>2</sub> electrode
Cysteine	Cucumber leaf	AAO	Ammonia gas sensor
Dopamine	Apple, avocado, banana, mushroom, potato	PPO	Oxygen electrode/carbon paste electrode
	Potato roots	PPO	Chemiluminescence
Ethyl paraoxon	Cucumber	AAO	O <sub>2</sub> electrode
Flavanols	Banana, potato, apple	PPO	Carbon paste electrode
Fluoride (and phosphate)	Asparagus	Asparagus peroxidase	Carbon paste electrode
	Potato	PPO	O <sub>2</sub> electrode
Glutamate	Yellow squash	Glutamate decarboxylase	CO <sub>2</sub> gas sensor
Glutathione	Cucumber	AAO	O <sub>2</sub> electrode
Glycolic acid	Spinach leaves	Glycolate oxidase	Carbon paste electrode/chemiluminescence
Hydroquinone	Sweet potato	Peroxidase	Graphite paste electrode
Mycotoxins	Mushroom	Tyrosinase	Carbon paste electrode
Oxalate	Spinach, banana peel	Oxalate oxidase	O <sub>2</sub> electrode
Paracetamol	Avocado	PPO	Graphite electrode
Pectin	Orange peel	Pectin esterase	Carbon paste electrode
Peroxide	Grape, asparagus, horseradish root	Catalase, horseradish peroxidase	O <sub>2</sub> electrode, carbon paste electrode
Phenol, <i>p</i> -cresol, <i>p</i> -chlorophenol	Mushroom	Tyrosinase	Carbon paste electrode
Pyruvate	Corn kernel	Pyruvate decarboxylase	CO <sub>2</sub> gas sensor, fiber-optic CO <sub>2</sub> sensor
Sulfoxide(s-methyl-L-cysteine sulfoxide)	Cabbage leaves	Allinase	NH <sub>3</sub> gas sensor
Tyrosine	Sugar beet	Tyrosinase	O <sub>2</sub> electrode
Urea	Soybean, jack bean, chrysanthemum	Urease	NH <sub>3</sub> gas sensor, chemiluminescence

centered on the fact that they contain many naturally occurring enzymes. The early attraction to the use of banana for the development of tissue-based biosensors is due to the fact that they are very rich in a copper-containing enzyme, known as ‘polyphenol oxidase (PPO)’, which can catalyze the conversion of dopamine to a quinone. PPO is well known for its inducement of browning in fruit and vegetables. This process, known as ‘phenolic oxidation’, has a positive role in disease resistance and possibly in photosynthetic regulation. The high level of PPO in banana has been readily exploited simply by placing a slice of the fruit on the surface of a dissolved oxygen electrode to produce a tissue-based biosensor for catecholamine. Common among the fruits and vegetables that have attracted interest for construction of tissue-based biosensors, as listed in **Table 1**, are avocado, banana, cabbage, cucumber, mushroom, potato, spinach, yellow squash, and zucchini.

Apart from some of the already highlighted benefits in using some tissue materials, the use of plant and animal tissues for the fabrication of tissue-based biosensors have the following specific advantages: (1) availability of tissues in abundance; (2) relatively high enzyme concentration; (3) availability of the additional components, such as co-factors, required for optimum catalytic activity; (4) access to enzymes that may not be available in isolated form; (5) high stability of enzymes in natural environment; (6) easier use for preparation of biosensor; and (7) very low cost compared to isolated enzymes. However, as can be expected, there are also some disadvantages in using animal and plant tissues for the construction of biosensors. A common problem experienced with this approach in earlier studies is mainly associated

with the difficulties in achieving adequate immobilization of the tissue materials. The use of thick layers of tissues, as a means of improving mechanical stability, resulted in very slow response times (10–30 min or more), as it act to create a long diffusion path between the solution and the electrode surface. For this reason, thinner layers of tissue materials are now commonly used and this has resulted in the reduction of the response time to less than 1 min in some cases, but typically not more than 10 min, as indicated in **Table 2**. In some cases, the use of homogenized tissue materials, for example, within a carbon paste matrix, has resulted in even more substantial reduction of the response time down to 30–40 s or less.

Another notable disadvantage of tissue-based biosensors is that their use is sometimes limited by interference from other enzymes or substances present in the tissues. However, several new approaches have reported for reducing these effects and in some cases taking advantage of the copresence of more than one enzyme for multicomponent analysis or the elimination of an interferant(s).

The principles and some of the important considerations in the development and use of tissue-based biosensors are described below. Also, some specific examples of the existing tissue-based biosensors that have employed a wide range of plant and animal tissues for the detection of a wide range of substances are discussed.

## Principles and Important Considerations

The working principles and operation of tissue-based biosensor are similar in many respects to those of the

**Table 2** Reported response times and lifetimes for some plant-tissue-based biosensors

<i>Substrate/analyte</i>	<i>Plant tissue</i>	<i>Response time (min)</i>	<i>Lifetime (days)</i>
Alcohol	Mushroom	2	
Atrazine	Potato		8–14
Catechol	Potato	3	1–2
Dopamine	Mushroom	4–9	120
Ethyl paraoxon	Cucumber	2	
Flavanols	Banana, potato and apple	40 s	68
Fluoride	Asparagus	1	12
Glutamate	Yellow squash	10	7
Glutathione	Cucumber		60
Glycolic acid	Spinach leaves	<1	12 (amperometry)
		1	> 30 (chemiluminescence)
Oxalate	Spinach	2–7	
Pectin	Orange peel		2
Peroxide	Grape	1	> 17 (O <sub>2</sub> electrode)
	Asparagus	2 s	> 30 (carbon paste)
Pyruvate	Corn kernel	6–12	7
Tyrosine	Sugar beet	5–10	8

**Figure 1** Schematic diagram of the arrangement of a tissue-based membrane biosensor: (A) slice of tissue; (B) bovine serum albumin conjugate layer; (C) carbon dioxide gas permeable membrane; (D) O-ring; (E) internal electrolyte solution; (F) pH-sensing glass membrane; (G) plastic electrode body. (Reproduced with permission from Kuriyama S and Rechnitz GA (1981) *Analytica Chimica Acta* 131: 91.)

conventional enzyme electrodes made from purified enzymes. However, a tissue-based biosensor is different in that it requires the placement of the tissue layer in an intimate contact with the chosen sensing electrode or other transducer that converts the biocatalytic reaction into a measurable analytical response, as illustrated in **Figure 1**. In most cases, the response to the associated biocatalytic reaction is usually measured by either amperometry or potentiometry. However, it is worth noting that amperometric detection is by far the most common detection mode used with tissue-based biosensors for the determination of various substances. The detection by amperometric and potentiometric modes are usually accomplished by combining the tissue with a dissolved oxygen electrode, a carbon paste electrode, or other gas electrodes, such as  $\text{CO}_2$  (**Figure 1**) and  $\text{NH}_3$  sensors. The optimization of the tissue and sensing electrode combination requires consideration of the influence of operational conditions, such as choice of tissue material (plant or animal), tissue thickness, choice of membrane, pH, buffer composition, and applied potential.

Another useful consideration is a knowledge of the physiology and metabolic processes of cellular material that can be beneficial for selecting appropriate tissue section(s) with high biocatalytic activity for the development of a reliable tissue-based biosensor. Such knowledge can also be helpful for characterizing and identifying interfering metabolic pathways. The transport of the substrate and of the product into, within, and out of the immobilized tissue forms the general basis for the response mechanism of tissue-based biosensors. Hence, with an understanding

of the tissue composition, it is also possible to exploit multiple enzymatic processes where several enzymes are present. The use of a combination of a tissue and a purified enzyme, as a hybrid, can also be considered for enabling the occurrence of multiple enzymatic processes in tissue–enzyme hybrid systems.

The potential for the coexistence of several enzymes in tissue materials can also be a major drawback as it can affect the selectivity of the device when used in complex sample media. Some of the strategies that have been employed for improving the selectivity of tissue-based biosensors include the use of activators to promote the primary reaction, inhibitors to suppress the undesirable reactions, or preincubation of the desired substrate. Under favorable conditions, the multienzyme activity of the tissue can be exploited for the detection of multicomponents in real samples. For example, with amperometric detection, such multicomponent detection may require the application of different potentials to achieve improved selectivity.

The problems of batch-to-batch reproducibility that were experienced in the early development of tissue-based biosensors were mainly associated with the difficulty in obtaining fresh and uniform sources of biocatalytic activities. Various attempts have been made to overcome these problems by use of a number of strategies, such as the use of plant tissue culture to produce fresh and consistent source of the biocatalytic activity, use of tissue homogenate, and pretreatment of tissue materials to remove possible interfering substances. Despite the batch-to-batch reproducibility problems, the recently reported analytical reproducibility (based on repeated analysis with the same tissue-based biosensor) has improved considerably, now commonly ranging from 0.3% to 4.0% relative standard deviation (RSD). In some cases, treatment of the tissue-based biosensors with a preservative, such as sodium azide, has also been found to improve performance by preventing bacterial growth and extending the lifetime of the biosensor.

Besides the availability of plant and animal tissues that contain the necessary enzymes and the associated issues with their use as described above, some of the other important considerations in the development and use of tissue-based biosensors include immobilization method, response time, and lifetimes. The significance of each of these factors is discussed below.

### Immobilization of Tissues

The physical retention of plant or animal tissues with either a membrane (**Figure 1**) or by incorporation

**Figure 2** A simplified illustration of a carbon paste banana-based electrode. (Reproduced with permission from Eggins BR, Hickey C, Toft SA, and Min Zhou D (1997) *Analytica Chimica Acta* 347: 281.)

into a carbon paste matrix (**Figure 2**) are the common methods of immobilization used for the construction of tissue-based biosensors. This is due to the fact that the matrices in which the tissues house the enzymes are already optimized and can, thus, be used directly in either of these ways. Consequently, in cases where the enzymatic activity is membrane bound, the use of tissues has a particular advantage over the use of purified enzymes. However, it is important to note that the choice of membrane or electrode components (in the case of carbon paste electrode) must enable the diffusion of the substrate into the biocatalytic enzyme layer of the tissue, while also preventing the diffusion of the biocatalyst away from the electrode surface. Suitable membrane materials for this purpose, in the case of the former, include cellophane dialysis membranes and nylon webbing of 150  $\mu\text{m}$  pore size. The diffusion of substrate and product to and from the tissue layer has been found to be unrestricted by both of these membranes. Other immobilization approaches that have attracted some interest in the fabrication of tissue-based biosensors include the use of alginate and hydrogels.

### Response Time

The ultimate test of the adequacy of the choice of immobilization of tissues by retention with a

membrane at a tip of an electrode or by incorporation into a carbon paste electrode is the achievable response times for substrate measurements. Depending on the electrode used in combination with the tissue, the response time can generally, as indicated by the data in **Table 2**, vary from less than 1 min to 10 min. Other factors that can influence the response time include tissue thickness, solution pH, membrane permeability, temperature, and stirring rate. In general, the response time increases with decreasing substrate concentration. It has been demonstrated that the two important factors that influence electrode response times are the tissue thickness and the effective solution substrate diffusion constant. To this end, the extent of external stirring influences the effective diffusion, while the bulk solution substrate diffusion coefficient influences the response time.

In terms of the choice of immobilization method, it is now widely accepted that the incorporation of the tissue into a carbon paste matrix is more effective for obtaining quick response and recovery times. A specific advantage of this immobilization approach is that the tissue becomes an integral part of the sensing electrode and, thus, enabling the achievement of not only a quick response time, but also very low detection limits. Another advantage is that, where necessary, it is possible to coimmobilize other reagents, such as redox mediators within the mixed tissue-carbon paste matrix. The nature of the mixed tissue-carbon paste matrix has also enabled the use of different designs, such as for thin-layer flow detectors and in miniaturized electrodes. **Figure 2** shows a simplified illustration of the process involved in the preparation of a carbon paste tissue-based electrode. Evidently, with the availability of an adequate plant tissue, this type of tissue-based biosensor can be prepared very quickly.

Other approaches that have been used for the immobilization of tissues for the construction of tissue-based biosensor include packing of tissues materials within the micropores of a porous carbon electrode, entrapment of tissue cells into electrochemically grown polymers, and incorporation into minireactors or column for flow analysis.

### Lifetimes

The usefulness and effectiveness of a tissue-based biosensor can be evaluated by its sensitivity, response time, detection limit, linear concentration range, and lifetime. The stability of the biocatalyst enzyme in the chosen tissue ultimately dictates the lifetime of a tissue-based biosensor. Factors that can affect the stability of the biocatalyst enzyme in the tissue include the chosen immobilization method, solution

pH, bacterial growth, storage conditions, and the presence of activators or inhibitors. Depending on the chosen tissue material, the lifetime of the biosensor can range generally from 1 to 30 days. However, as indicated by the data in Table 2, tissue-based biosensors with lifetimes longer than 3 months have been reported in recent years.

## Plant Tissue Biosensors

As discussed earlier, several fruits, plant leaves, and vegetables have been successfully used to develop tissue-based biosensors for a wide range of substances. Table 1 shows that a very diverse range of plant tissues have been used to develop various tissue-based biosensors with excellent detection limit and linear concentration range, commonly in the micromolar range. As indicated previously, the reproducibility of most of these biosensors is within 0.3–4.0% RSD and reported tissue-based biosensors for dopamine, glycolic acid, glutathione, and peroxide have lifetimes greater than 1 month and, in some cases, up to 4 months (Table 2). These various plant-tissue-based biosensors have been applied to the determination of various substances in a diverse range of sample materials, such as alcoholic beverages, river water, wastewater, urine, serum, whole blood, pharmaceutical preparations, cosmetic creams, vegetables, and fruits.

The information in Table 1 shows that plants that contain PPO such as apple, avocado, banana, coconut, mushroom and potato have attracted wide use for the construction of tissue-based biosensors for determination of atrazine, catechol, dopamine, and paracetamol. Also, plant materials that contain ascorbic acid oxidase (AAO), such as cabbage, cucumber, green zucchini squash, yellow crook neck squash, have attracted considerable interest in the development of tissue-based biosensors for the determination of ascorbic acid, glutathione, and organophosphorus pesticide. It is important to note here that while the determination of ascorbic acid was based on the direct biocatalytic effect of AAO, the measurement of glutathione and organophosphorus pesticide (ethyl paraoxon) was based on the inhibitory effect of these substances of the biocatalytic activity of AAO. Another common enzyme that is often used (Table 1) is tyrosinase, which was obtained from plant materials, such as mushroom and sugar beet, and used for the construction of tissue-based biosensor for the determination of mycotoxins, tyrosine, and phenolic compounds. It is also important to note that the use of some of the tissue-based biosensors for monitoring organic-phase biocatalytic

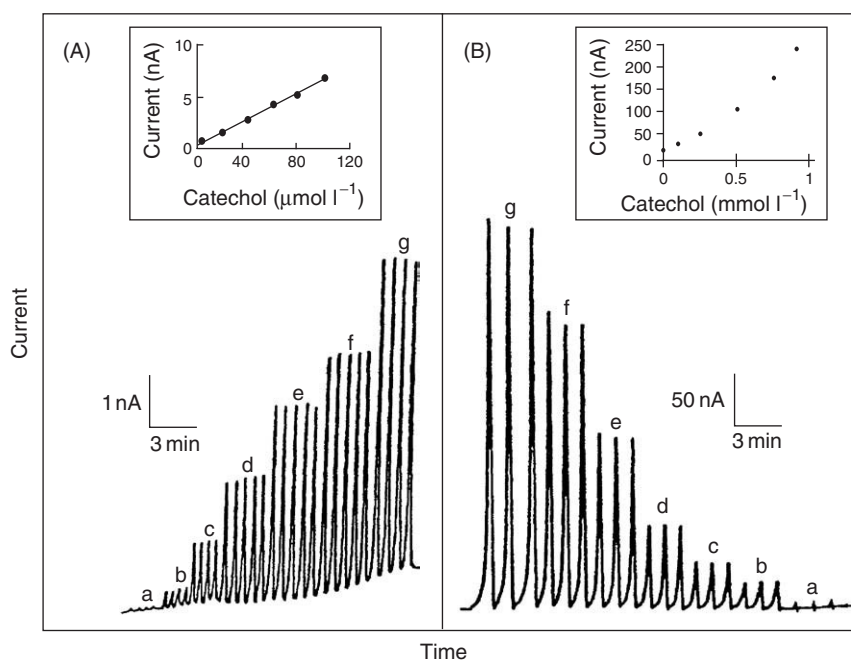

**Figure 3** Amperometric FIA detection of (A) different alcohols and of alcohols in (B) alcoholic beverages with a yeast-based biosensor. Alcohols in (A) are: (a)  $1 \text{ mmol l}^{-1}$  1-amyl alcohol, (b)  $1 \text{ mmol l}^{-1}$  1-butanol, (c)  $1 \text{ mmol l}^{-1}$  1-propanol, and (d)  $1 \text{ mmol l}^{-1}$  ethanol. Beverages in (B) are: (a) Polish vodka (Polanex), (b) red wine (Gallo), (c) white wine (Reunite), and (d) beer (Miller Lite); diluted 1:100 000, 1:100 000, 1:20 000, and 1:10 000, respectively. Inset is the corresponding batch current-time response for the addition of the different alcohols. (Reproduced with permission from Kubiak WW and Wang J (1989) *Analytica Chimica Acta* 221: 43.)

reactions has been reported. Also, an increasing use of these biosensors for flow injection analysis (FIA) and as detectors for high-performance liquid chromatography has been reported. Figure 3 shows the successful use of a yeast-based carbon paste bioelectrode for the FIA measurement of different alcohols and the determination of alcohol in alcoholic beverages. Also, a rapidly responding tissue- and microbe-based carbon paste electrode has been successfully used as an electrochemical detector for liquid chromatographic determination of *p*-cresol, dopamine, and ethanol.

The successful exploitation of the multienzyme composition of plant tissues in eliminating interferences and, hence, improving the selectivity and stability of tissue-based biosensors have also been reported. The presence of AAO in zucchini has been successfully used to eliminate ascorbic acid interference from the determination of dopamine or norepinephrine. Also, the incorporation of papaya tissue into a carbon paste matrix has been effectively used to destroy surface active proteins.

Another area of interest is the use of tissue-based biosensors in bioreactors. Figure 4 shows the successful use of a coconut-tissue-based bioreactor for the determination of catechol in river water and wastewater. Evidently, catechol concentrations can be determined reliably in these samples by this approach down to the micromolar levels.

**Figure 4** Quantification of catechol in (A) river water and (B) a paper plant waste water by FIA with a coconut tissue-based biosensor. (a) response for sample in absence of coconut bioreactor; (b) response for sample in presence of coconut bioreactor; (c)–(g) 20–100  $\mu\text{mol l}^{-1}$  spike for river water or 0.1–0.0  $\text{mmol l}^{-1}$  for waste water. (Reproduced with permission from Lima AWO, Nascimento VB, Pedrotti JJ, and Angnes L (1997) *Analytica Chimica Acta* 354: 325.)

## Animal Tissue Biosensors

In addition to plant tissues, several animal tissues have also been used to develop tissue-based biosensors. Some of the animal tissues that have been employed for this purpose and the associated enzymes and substrates are listed in **Table 3**. Evidently, two of the enzymes and substrates that have attracted considerable interest in the use of animal tissues for tissue-based biosensors are cytochrome *c* and lactate dehydrogenase for the determination of formic acid and lactate, respectively. Some of the other substances that have been determined with animal-tissue-based biosensors include adenine, alcohol, cholesterol, choline, guanine, and uric acid.

In one study, sliced or smashed (paste) porcine kidney was used, as a source of glutaminase, in conjunction with a conductance-surface acoustic wave resonator and a pair of parallel electrodes to develop a tissue-based biosensor for the determination of glutamine. The glutaminase in the porcine kidney catalyzed the hydrolysis of glutamine. The biosensor achieved a detection limit of 340  $\mu\text{mol l}^{-1}$  for glutamine and a wide linear concentration range of 680–6800  $\mu\text{mol l}^{-1}$ . The biosensor response was reproducible, achieving an RSD of 2.5%.

In another study, a slice of bovine liver attached to an oxygen electrode was used to construct a

tissue-based biosensor for hydrogen peroxide. The response of the biosensor to hydrogen peroxide was sensitive and stable. Other similar liver tissue biosensors for hydrogen peroxide have been reported and their lifetime is  $\sim 8$  days. Also, fluoride inhibition of the activity of liver esterase has been used to determine fluoride concentration down to 0.1  $\mu\text{mol l}^{-1}$ .

A recent interest in using animal tissue for construction of tissue-based biosensor involves the use of insect antenna. The olfactory abilities of up to 250 insects have been investigated to date. Of particular interest is the ability of these insects to detect odors. The two main groups of odor substances that these insects can detect are pheromones and host plant odors. These insects can detect  $\sim 250$  pheromones with very high sensitivity and selectivity, while  $\sim 400$  host plant odors can also be detected. The insect antenna is the key odor recognition component, consisting of several segments, equipped with sensilla that contain between one and three neurons that have special receptors for some odor substances. The use of the olfactory abilities of insects for the development of tissue-based biosensor has been reported. This involves the coupling of an insect (Colorado Potato Beetle) antenna to a field-effect transistor to detect the concentrations of the odor of *cis*-3-hexen-1-ol down to the parts per trillion

**Table 3** Some animal tissues that have been used for the development of tissue-based biosensors

<i>Animal tissue</i>	<i>Enzyme</i>	<i>Substrate/analyte</i>

## Introduction

The use of human senses to measure and interpret flavor and sensory characteristics of foods, beverages,

or other materials is called sensory evaluation. All the human senses are involved in describing and measuring what can be detected by laboratory instruments (e.g., volatile chemicals by gas chromatography). The article consists of a general guide to the sensory and consumer testing methodologies and gives the basic principles of sensory evaluation. Sensory evaluation comprises a set of techniques that can provide analytical information of the sensory attribute of food or nonfood products to define the

## Introduction

The use of human senses to measure and interpret flavor and sensory characteristics of foods, beverages,

or other materials is called sensory evaluation. All the human senses are involved in describing and measuring what can be detected by laboratory instruments (e.g., volatile chemicals by gas chromatography). The article consists of a general guide to the sensory and consumer testing methodologies and gives the basic principles of sensory evaluation. Sensory evaluation comprises a set of techniques that can provide analytical information of the sensory attribute of food or nonfood products to define the

technical specification of the product and the hedonic perception of that product as defined by the user/consumer.

## Sensory Panels

Depending of their role, different types of panels with different sensory qualification can be distinguished.

### Expert Panel

It is composed of carefully trained and selected respondents with high degree of sensory sensitivity, discriminative ability, and experience of sensory methodology; the experts have developed a long-term memory and are able to make consistent and repeatable sensory assessments of products. Expert assessors can have additional experience as a specialist in the products and the process.

### Trained Panel

It comprises selected and trained assessors who have undergone sensory training and have experience of the methods under investigation. These people have developed the ability to perceive the differences and describe sample products' sensory characteristics and their intensity.

### Consumer Panel

In contrast to all other types of panels, consumers are not given any training, and therefore are only employed for preference and acceptance tests. Their answers are subjective and food acceptance is influenced by many factors like personal experience, sex, age, regular use of the product, eating habits, and social and nutritional aspects.

Consumers are recruited and screened for eligibility to participate in the test from a consumer database consisting of prerecruited consumers and are representative of the segment of population that regularly purchase or is expected to use the product or the product category.

## Panel Selection and Development

### Threshold and Sensitivity

The human sensory apparatus varies in sensitivity from person to person. Therefore, in the selection of panelists for sensory evaluation purposes the first step is to establish the limits of their sensory capacities by determining their perception thresholds for basic tastes, flavor, and odor recognition.

There are several definitions of threshold. The 'detection threshold' is defined as the lowest stimulus eliciting a sensorial response, even though no identification can be reached. The 'recognition threshold' or 'identification threshold' is the level of stimulus at which the specific stimulus can be identified. The 'differential threshold' or 'just noticeable' difference, is the minimum increase in a stimulus required to detect a difference in the perception.

There is also a 'terminal threshold', which is the magnitude of stimulus at which there is no increase in the perception of stimulus increasing.

A series of increasing concentrations of a chemically pure stimulus material in a neutral substrate (water or oil) may be used to determine sensory thresholds to those compounds. The assessors have to indicate the concentration at which stimulus is perceived for two successive concentrations. Increasing concentrations of sucrose, sodium chloride, citric acid, and caffeine are used for the basic tastes sweet, salt, acid, and bitter. Likewise, the olfactory threshold is determined by using some odorants in aqueous or alcoholic solutions (absolute ethanol is often used as a solvent), to measure the ability of the panelists to identify an odor impression and evaluate their odor memory.

### Background Information and Screening of Candidates

The most important problem in sensory testing is that although the sense receptors make an objective detection of food product, the personal psychology of consumers may lead them to have subjective judgments based on personal interpretations. An accurate sensory analytical methodology has been developed to obtain significant sensory results. This methodology requires trained sensitivity and a reliable and reproducible rating of small differences in sensory perception and excludes any subjective interpretation.

The most important criteria to be controlled when determining whether panel candidates are suited to the group dynamics are: health (normal sensitivity, infrequent colds, good dental condition, absence of specific allergies, diabetes, hypertension); motivation (willingness and interest in full participation); feeling of responsibility; sensory memory (ability to memorize many different odor and flavor impressions); ability to communicate and describe the sensory perceptions; ability to make judgments (honesty, self-criticism, objectivity, independence); avoidance of bias; ability to make decision (not easily discouraged, not timid); team

spirit; availability; attitude to foods (lack of aversions, or strong dislike for products, particularly those to assess, together with any cultural or ethnic reason for not consuming certain foods); and punctuality.

During this phase, panelists are screened and selected for their sensory acuity and potential for describing and communicating their sensory perception. Particularly, each candidate's ability to detect and describe, by screening tests, differences in flavor or texture characteristics and their intensities by scaling methods is checked, ability that will be better developed by suitable training. The choice of the screening test reflects the requirements of the selected assessors and the test are tailored to particular products to be evaluated.

### Training

The training program depends on the future role of the panel: to develop a descriptive panel that is able to identify and describe a wide range of sensory characteristics. The training is designed to:

- familiarize the assessors with test procedures;
- develop descriptive ability (ability to recognize and describe sensory stimuli);
- improve their sensitivity and sensory memory;
- learn to quantify their sensory perception.

In the training program, twice the number of assessors required in the final panel is recruited. Panelists are informed on how the perception of taste and odor occurs by lectures and demonstrations, and receive instructions on the technical procedure of tasting, such as size of mouthful to take, number of chews, and whether to be swallowed or not.

The next step of the training program is to develop a terminology system: a common list of terms for the whole panel and of which the panel share a common understanding of the meaning of each term. Sensory concepts are aligned and recognition of specific attributes can be re-enforced by the use of appropriate chemical or physical standards.

The subsequent step consists in training assessors to rate the perceived intensity of some descriptors of foods on an evaluation scale. Panelists learn to quantify their perception, initially by ranking series of single odor or taste or texture stimuli with respect to the intensity of a particular characteristic, then quantifying the perception on the evaluation scale. The test samples used are model systems: for instance, a single taste or flavor compound in water or other neutral media; or solid or semisolid materials differentiated in their texture properties; or samples obtained by spiking product samples with a flavor

compound, such as drinks added with an extra quantity of citric acid to increase the intensity of this acidic taste. The best approach is to start with simple products first, and then pass to more complex products when the assessors become more competent.

Panelists will define the direction of the scale (from minimum to maximum, or from maximum to minimum) and decide on the words needed to anchor the scales, such as 'none' to 'extreme' or 'slight' to 'strong'. Quantitative references can be used for defining anchors points at the end of each attribute. This is done, for example, using references or made-up samples to which a known concentration of a flavor substance has been added to remind the assessors of the exact meaning of a particular value on the sensory scale.

### The Test Room

Sensory evaluations are conducted in a distraction-free environment, to ensure panelists are not biased, or their sensitivity compromised. The test room should be at a comfortable temperature and ventilated with odor-free air. Lighting must be adapted to the testing using white light, which does not throw shadows. Colored lights can be used if appearance needs to be masked when only a flavor evaluation is required. Sound should also be restricted. The assessors must be comfortably seated in separate and not too narrow booths, in order to reduce distractions and panelists interaction during individual work. The booths should be provided with writing and spitting facilities and water for rinsing mouth. Plates and glasses for serving foods must be odorless and of neutral appearance so that no bias will be introduced.

## Sensory Evaluation Methods

### Discriminative Analysis

Discrimination analysis consists of difference and sensitivity tests. All of them are nonparametric; that is, they can determine whether two products differ, but they cannot determine how much. They are used when a simple answer is needed to a very simple question, i.e., whether or not there is a perceptible difference between two samples. It is possible for two samples to be chemically different in formulation but for human being not to perceive this difference.

#### Difference tests

*Paired comparison* There are two analytical sensory forms of this test: the difference paired comparison (also called as the simple difference test) and the

directional paired comparison (also known as the 2-alternative forced-choice or 2-AFC test).

The first technique is used when the experimenter wants to determine whether a simple sensory difference exists between two products (two-sided test) without specifying the dimension(s) (attributes) of the potential difference. Two odd or matched pair coded samples (A, B) are simultaneously evaluated in a randomized order of presentation between the assessors with equal number of the four possible serving sequences. (AB, BA, AA, BB). About 25 to 50 presentations are required to determine differences. The probability ( $P$ ) that an answer occurs by chance is  $1/2$ .

In the directional paired comparison method the experimenter wants to determine whether the two samples differ in a specified dimension, such as saltiness, hardness, crispness; samples are simultaneously presented to the assessors in two possible combinations (AB, BA), randomized across panelists, with an equal number of panelists receiving either sample A or sample B first. The assessors have to choose the sample within the pair that presents the higher intensity of a specified characteristic (one-sided test).

In both forms of the test the null hypothesis is that no distinction can be made between the products: in the two-sided test the alternative hypothesis is  $P_a \neq P_b$ ; in the one-sided test it is  $P_a > 1/2$ .

**Triangle** Three coded samples (two of which are the same and one is different) are distributed to the assessors in six possible sequences of two products A and B (AAB, BBA, BAB, ABA, BAA, ABB) that should be counterbalanced across all panelists. The assessors must indicate which the odd sample is. A forced choice is required also if the selection is based on a guess. These combinations of samples are distributed at random in groups of six among the assessors. In order to balance the results (each sequence uses an equal number of times), the number of assessors taking part in the test should be preferably in multiples of six.

The triangle test allows the sensory analyst to determine if two samples are perceptibly different, but not in which attributes the samples differed.

The probability ( $P$ ) of picking the right or the wrong sample by chance is  $1/3$  and therefore the null hypothesis will be rejected in favor of the alternative hypothesis at  $P > 1/3$ .

**Duo-trio** In this test, the panelists receive three samples simultaneously: one sample identified as a standard and two coded samples, one of which is the same formulation as the standard. A forced choice is required. Panelists have to recognize which of the

coded samples matches the standard. The probability of selecting the matching sample is  $0.5$ .

**Three-alternative forced choice (3-AFC)** The test allows to determine if two products differ in the specified dimension and which sample is higher in perceived intensity of the specified attribute. Three coded samples (two of which are the same and one is different) are distributed between the panelists in randomized or balanced order in three possible combinations (AAB, ABA, BAA, or BBA, BAB, ABB). As for the triangle the null hypothesis is  $P = 1/3$ .

**A, non-A** This test is essentially a sequential paired difference test. Panelists receive and evaluate a first sample that is then removed. Then the panelists receive a second sample and are asked to indicate whether the two samples are perceived to be the same or not. Since the panelists do not have the sample available simultaneously they must mentally compare the two samples and decide whether they are similar or different.

Another historical version of this test, rejected at present, consisted in presenting a single sample with a choice of response as A or non-A.

Like the difference paired comparison method, the A-non-A test has four possible serving sequences (AA, BB, AB, BA) that are randomized across panelists, with each sequence appearing an equal number of times. As in paired comparison, the null hypothesis is of no distinction between the samples and the alternative hypothesis is  $P_a > 0.5$ .

**Two out of five** This is a difference test involving five coded samples, two of one type and three of a different type. The tasters are asked to group the two sets of samples. They evaluate the samples in sequence from left to right. There are 20 possible combinations of the five samples (AAABB, AABAB, ABAAB, BAAAB, AABBA, ABABA, BAABA, AB-BAA, BABAA; BBAAA, BBBAA; BBABA, BABBA, ABBBA, BBAAB, BABAB, ABBAB, BAABB, ABABB, AABBB) that are randomly selected when the number of judges is less than 20. This method is statistically very efficient (the null hypothesis is  $P = 1/10$ ) but is affected by sensory fatigue and by the difficulty of memorizing the samples, and therefore is not usually used in flavor testing.

**Ranking** It is used for the classification of samples according to a specified difference between samples, e.g., a particular attribute, characteristic, impression, or preference.

A set of samples are presented to each assessor in random order and compared simultaneously for a

single sensory attribute. Five samples are a reasonable upper limit and at least seven selected assessors should be recruited, preferably with the same level of qualification (e.g., untrained assessors, selected assessors, experts). The assessors assign rank 1 to the sample with the strongest or weakest intensity of the attribute according to the given instruction. Data are merely ordinal, and no information on the degree of the difference is collected. A variety of statistical methods to analyze the data is available such as the Friedman rank test of the Page test.

**Sensitivity tests** Sensitivity tests are frequently used to define a threshold for taint and off-flavor in products and to select panelists for their sensitivity to key flavor compounds or any other component that can contribute to the perceived flavor.

**Threshold** This is for the recognition of taste, odor, and flavor components. A series of solutions in order of physical concentration of the stimulus is used to determine the absolute threshold (ascending forced choice).

**Dilution** The dilution indicates the smallest amount of test material that can be detected. By preparing a dilution of an aqueous extract (food substance or chemical mixture) the single flavor component can be analyzed.

## Descriptive Analysis

Descriptive analysis involves the description of qualitative and quantitative sensory aspects of a product by a trained panel relying upon objective reference standards.

**Scaling procedure** Quantification of sensory data being the perceived intensity or liking requires some form of scaling procedure. This can simply involve ordering the sample on the basis of intensity or grading by placing them into categories that can be predefined on one or more attributes.

Sensory data can be collected in different ways according to the purpose of the study. Four methods of measuring the data using four scales can be mentioned.

**Nominal scale** Data are simply descriptive: a series of categories, which are identified and labeled using a name or a number, is listed; samples are classified into groups on basis of the frequencies of each category. They contain very little information because no quantitative relationships are established.

**Ordinal scale** Samples are ranked for a single specific characteristic. Ordinal data are used for 'category scaling'. The tasters are asked to rate the intensity of a sensorial stimulus by assigning a score on a limited verbal or numerical scale. The number of points on the scale used for the determination of the different flavor attributes can differ by 5, 7, 9, and 10 points. Usually a description is attached to each value. In this scale the data are merely ordinal and intervals are not equidistant. The size of the difference between two values cannot be assumed to reflect the difference between the perceived intensities.

**Interval scale** Panelists score the samples in a structured scale, in which each value is separated by a constant interval. The exact intervals vary according to tradition (nine-point hedonic scale, 100-point scale). The psychological error of 'central tendency', i.e., avoidance of the endpoint scale, is frequently observed in scoring. Alternatively, a nonnumerical or graphical scale can be used, consisting of a horizontal line on which panelists mark a position on the scale; the scale is then converted to centimeters for numerical analysis. Anchors are presented along with the experimental samples to illustrate minimum and maximum intensities within the test. Line scales permit fineness of differentiation among responses and are examples of continuous scales.

The feature of interval data is that equal differences between numerical values correspond to equal differences between perceived intensities of the properties measured.

**Ratio data** This method is an estimation of magnitude by comparison with a reference stimulus. Data are collected on a magnitude estimation scale. Panelists receive a reference sample to which any number that seems appropriate (unspecified modulus) or a prescribed value (fixed modulus) is assigned. All the other samples are scaled in comparison with the reference sample. And this scale can be open or limited by the highest and lowest standards provided. A ratio scale has the same properties as an interval scale and, in addition, the ratio between the value allocated to two stimuli is equal to the ratio between the perceived intensities of these stimuli.

**Consensus profiling** Also named flavor profile analysis, this technique was developed to provide aroma and flavor impressions, and assess feeling factors and aftertaste. Judgments are made by four to six selected and trained panelists who undergo an advanced training period in order to orient them to a particular product to be analyzed. They work

as a team to reach a consensus opinion. This method employs intensity scaling for each sensory impression and rating to indicate the fullness of numerous aroma and flavor perceptions. With the help of the panel leader, panelists develop the appropriate terminology. Reference standard and definition for each descriptor are also created during the training phase to improve the precision of the consensus description.

This descriptive technique does not require statistical analysis of the data: confidence is derived from the reliability of skilled panelists' collective judgment. The data are reported in tabular or graphic form. One disadvantage of this method is that the panel's opinion may be affected by a dominant personality so that not all the panel members provide an equal input to the consensus.

**Conventional descriptive profiling** Descriptive profiling encompasses techniques based on descriptive quantitative analysis (QDA), a profiling method developed during the 1970s in response to dissatisfaction with the lack of statistical treatment of data obtained with the consensus profile method and the need to describe and measure the sensory parameters with mathematical precision. The basic approach to profiling of the QDA technique establish that the data are not generated through consensus discussion, that the panel leaders are not active participants, and that the assessors rate the intensity of the sensory attributes individually and the results are averaged over individual rating of assessors.

Although many different types of rating scales are in use, continuous unstructured line scales, 90 or 150 mm long, anchored at the end by terms that define the limits for each attribute are the most used. Six to 15 trained panelists are usually employed.

Descriptive profiling techniques provide for the intelligent use of human subjects as measuring instrument. When properly trained, human subjects can be effective analytical instruments able to accurately analyze flavor and aroma attributes present in a food system, and to generate statistical comparisons of samples products.

Panelists first take part in introductory meetings and discussions in order to choose and develop terms appropriate to the aim of the tests. One of the main points of the discussion is to reach an agreement on the understanding of the different sensory attributes. All member of the panel have to characterize each sensorial perception in the same terms. Round table discussions are useful to the tasters for discussing both aroma and flavor record attributes and their intensities, and avoiding any disagreements and doubts about the terminology used in the sensorial

perception. In this phase, the panel prepares the score sheet containing the descriptive terms and provide an agreed definition for each term. The panelists also decide on the reference standards that should be used to anchor the descriptive terms.

Then the task of the assessors is to mark across the line the point that represents the intensity of their perceptions. Repeated judgments from each panelist for each sample are collected and arithmetic means of the score for each attribute are obtained. Panelists do not discuss the data after each taste session, to reach a consensus, but data are statistically analyzed to determine differences between the products and to control for panelists and panel performance.

Another feature of the method is the use of a graphic line scale that allows data to be presented clearly and easily. Each sensory attribute is presented by a graphic line radiating from the center as shown in Figure 1. The mean score of each parameter is located at the point on the scale corresponding to the intensity of the perception, and connected by lines in order to give a graphical profile of the descriptive results. The advantages of this kind of presentation are the following:

1. the different attributes in the comparison of the two different products are shown at a glance;
2. it provides a visual depiction of the appearance, flavor, and texture attributes of the products.

In any descriptive profiling program, before drawing any conclusion from the data, it is necessary to determine how the panelists are performing. When

**Figure 1** Quantitative descriptive analysis configuration of the aroma in orange juice samples. The average intensities for the various attributes are graphed on lines radiation outward from a value of 0 at the center point to a value of 9 at the outward perimeter.

panelists disagree, it is important to determine whether there is interaction due to a 'crossover effect' (not all the panelists rating the samples in the same order), or whether it is a matter of tasters seeing relatively small differences in intensity among the samples. Tasters may well be quite variable over time, very variable among themselves, and sometimes prone to bias.

**Free-choice profiling** The free-choice profiling technique was developed during the 1980s. According to this method each assessor develops his or her own list of descriptive terms instead of extensively training the panelists to generate a consensus vocabulary for the products or adopting common standards and agreed rating. Each panelist uses his or her unique list of term to evaluate the products. However, each individual assessor has to be able to use their developed vocabulary of terms consistently when evaluating the product. As for conventional descriptive profiling evaluations are replicated and assessors evaluated for their performance. A sophisticated multivariate statistical technique, known as the generalized procrustes analysis, it is used to analyze the data and to construct multidimensional maps that identify the descriptors that are commonly used to describe and discriminate between samples. With this technique each assessor's data are transformed into individual spatial configuration. These configurations from individual assessors are then matched by procrustes analysis to a consensus configuration that allows determining how different terms used by different assessors may be interrelated.

**Time-intensity profiling** The perceived intensity of sensory attributes can change as a function of time.

Time-intensity sensory evaluation consists in quantifying the continuous perceptual changes that occur in the specified attribute over time. Time-related methods have been used extensively to investigate the temporal behavior of tastants such as sweet and bitter stimuli and flavor release phenomena from food.

Continuous time-intensity scaling can be recorded using external devices such as strip-chart recorders, potentiometers, or computers. Computer data acquisition has facilitated the recording of time-intensity data: a scale is displayed on a computer screen and the panelists position the computer cursor on the scale to indicate the intensity of the attribute at each instant in time, using various data input methods such as moving a computer mouse or light pen, or joystick, or touching a touch-sensitive screen.

The following information can be obtained: the maximum intensity perceived during the time of

measurement, the time to reach the maximum intensity, the rate of intensity decrease after peak intensity (slope), the time to half-maximal intensity and to the estimation point, the duration of peak intensity, and the total duration of the sensation.

### Acceptance and Preference Testing

This section refers to the consumers' sensory tests used to evaluate product liking or to determine which of a series of products is the most acceptable or the most preferred.

Acceptance is an expression of higher degree of liking of a product, on a hedonic rating scale, which justifies the choice of one object over others. Acceptance or liking measurement can be done on single products and do not require comparison with other products.

Preference is an expression of positive attitude for an object and/or actual utilization. It is an expression of the level of liking. It includes the choice of one sample over another or more other samples.

**Preference test** There are different versions of preference tests.

*Paired preference test* In this test the assessors is presented with two coded products simultaneously and asked to identify the sample that it is preferred and offer a reason for preference. The test design ensures that the two possible sequences of samples (AB and BA) are balanced across panelists, so that each sample is assessed equally often in first or second position. Usually consumers are obliged to make a choice also when they have no preferences. However, there is a nonforced preference version of the test. A no-preference option is used in the score sheet and reported although usually excluded from the analysis.

*Multisample ranking for preference* This test is equivalent to the ranking test used in sensory difference testing except that attributes specified is preference or liking.

### Acceptance test

*Hedonic scaling* The method consists in recording the extent of liking of a product on a degree of liking scale that runs from 'extreme dislike' to 'extreme like'.

Hedonic scaling can be achieved using a five-, seven-, or nine-point scale. Such category scales are based on nonequal interval spacing, and for this are treated as ordinal scales. An alternative approach is to ask respondents to indicate their hedonic response

to the samples on an interval continuous scale or a line scale, sometimes anchored by like and dislike on each end, which assumes that intervals are equal and data can be summarized by averaging liking scores.

**Qualitative methods** Qualitative research methods are used to generate important terms for sensory attributes and to identify those attributes that are critical in consumer acceptance, i.e., positive attributes that have to be maximized in the product; and the characteristics that consumers do not like and think that must be minimized or eliminated from the product.

The purpose of the qualitative research analysis is to optimize product acceptance, to develop product prototypes, to establish criteria for data collection in a quantitative study, to gather information on how a product or product category is perceived, and the language that a consumer uses to talk about a product category. Group interviews are applied also in the early stage of descriptive analysis for terminology development for the use in the descriptive scorecard. This can help to ensure that everyone is speaking the same language.

Qualitative methods include one-on-one in depth interviews, group interviews, and focus group. The most commonly used qualitative research method is the focus group.

**Focus group** Focus groups vary in size and ideally consist of 8 to 12 participants. The consumer panel must be representative of the target population and it is drawn from the target population. The target population is defined as the segment of the population that regularly purchases or uses the product category.

**Quantitative methods** There are three types of quantitative affective tests using: (1) an in-house panel of consumers (laboratory test), (2) a field test

of consumers at home (home test), and (3) a field test in an institution (institutional test).

**Laboratory test** It is used when a controlled environment (odor, light, temperature, etc.) and product preparation (portion size, serving temperature) are needed.

**Home test** The aim of this test is to collect the opinion of an item by the whole family. The disadvantage of this method of data collection is the inability of the supervisor to control directly the validity of the testing procedure.

**Institutional test** Here data are collected by interview or questionnaire in institutions like markets, factories, hospitals, and schools. The advantage of this technique is that the testing procedure can be controlled. The disadvantage is the limited number of questions that can be asked to consumers.

## Introduction

Sequential injection analysis (SIA) was developed in 1989 at the laboratories of the Center for Process

Analytical Chemistry (CPAC), at the University of Washington. CPAC industry collaborators had been developing innovative instrumentation and methodologies using flow injection analysis (FIA), but had identified that the requirement for a different manifold for each analytical method and the relatively high maintenance of peristaltic pumps were major shortcomings when FIA was applied to process

analysis. These inadequacies challenged researchers at CPAC to develop a simpler, more robust, automated liquid manipulation system.

The earliest experiments were performed with a disposable syringe, which acted as both pump and detection cell, and a multiposition valve. Upon reverse movement of the plunger, new reagents were drawn into the syringe, mixed by the resultant turbulence and the absorbance measured. Forward motion of the plunger expelled the reactants from the system in preparation for the next analysis. It was soon realized that the high degree of carryover and large reagent usage made this approach unsuitable for process analysis. Around this time Graham Marshall joined the project under the direction of Professor Jarda Ruzicka. Marshall noted that it was easier and more effective to flush the reactants from small internal diameter tubing (0.8 mm) than from the syringe barrel and consequently positioning of the detector was altered such that it was situated between the pump and multiposition valve.

In their first report of SIA in 1990, Ruzicka and Marshall operated a sinusoidal pump in reverse, sequentially aspirating reagents through a detection cell, giving rise to a primary response. This was followed by flow reversal (to expel the waste) and generated a secondary response that was broader and of lower intensity. Subsequent work by Gübeli, Ruzicka, and Christian moved the detection cell to the opposite side of the multiposition valve, resulting in a single peak; an approach that has been adopted by most SIA practitioners.

SIA has since rapidly established itself as a powerful and versatile flow-based sample-handling method as the instrumental setup facilitates the use of different chemistries without the need to reconfigure the manifold (see **Figure 1**). With the capacity to

**Figure 1** The number of SIA publications between January 1990 and December 2002, as reported by the chemical abstracts service SciFinder Scholar. Key words were sequential injection and SIA.

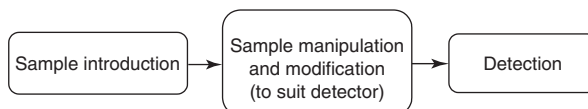

stack, in any order, precisely defined zones of sample and reagent that are mixed (by means of diffusion and flow reversal) to yield detectable products, SIA can be easily manipulated to incorporate a variety of detection methods and applied to a diverse range of analytical applications. This article provides a general overview of the principles of operation, instrumentation, detection techniques, and analytical applications of SIA.

## Principles of Operation

The functions used by SIA in order to perform an analytical method are similar to those used in FIA and are depicted in **Figure 2**. A zone of sample is aspirated into the instrument, the required chemistry performed, and the resultant product detected and propelled to waste. As with FIA, integral to the successful operation of SIA is the principle of controlled partial dispersion with reproducible sample handling. This is achieved using computer-controlled instrumentation comprising a selection valve, pump, and detector operating synchronously (see **Figure 3**). The instrumental configuration of SIA (**Figure 3**) allows the use of multireagent chemistries by sandwiching the sample between a variety of differing reagents and/or carriers.

SIA sequentially aspirates aliquots of sample and reagent into a holding coil by selecting the required reactant reservoir (with the selection valve) and operating the pump in reverse (see **Figure 4A** and **B**). Subsequent forward propulsion of this 'stack' of reactants results in mixing and formation of a zone of detectable product (see **Figure 4**). The order in which reactant zones are aspirated are dependent on the chemistry being used. Modifications of volumes and flow rates are achieved using appropriate computer control software.

The power of SIA is evidenced in that some methodologies and chemistries are unique to SIA, and cannot be or are difficult to perform, with manual or other analytical techniques. The operational principles of SIA allow the potential for use with harsh and demanding matrices such as strongly acidic, alkaline, or organic solutions. This is due to the aspiration of reagent zones into a holding coil such that the reactants never make contact with the pump.

**Figure 2** The analytical functions performed by SIA.

**Figure 3** A schematic diagram showing a typical SIA manifold.

**Figure 4** Schematic diagram illustrating: (A and B) the pump operating in the reverse mode to aspirate a stack of sample and reagent and (C) flow reversal and the formation of a zone of detectable product, where the arrow indicates direction of flow.

## Dispersion

Not only does the flowing stream in SIA serve to propel the sample toward the detector; it also promotes mixing of the reactant zones to generate a detectable product. This process is commonly referred to as dispersion and can be defined as the dynamic merging of reactant zones as a result of forward and reversed flow through narrow bore tubing. As this merger is dynamic, the dispersion (and consequently the chemical reaction) never reaches equilibrium. Reproducible mixing is achieved by maintaining stringent control over the parameters affecting dispersion. These parameters include sample and reagent volumes, aspiration order, tubing internal diameter, tubing length, flow rate, number of flow reversals, type of reactor, and the geometry of valve,

**Table 1** Some of the terms that have been used to describe the dispersion in SIA

Term	Definition
$D$	Degree of dispersion
$S_{1/2}$	The volume required to reach a dispersion of 2 at the peak maximum
$P$	Degree of zone penetration

detectors, and connectors and are easily controlled. Two types of dispersion occur in SIA, axial and radial, which occur in the direction of and perpendicular to the direction of flow, respectively. Axial dispersion causes greater dilution and predominates in straight tubing whilst knitted/knotted reactors promote radial dispersion and minimize dilution. As might be expected, the use of more than one flow reversal results in increased dispersion and broadening of the signal. The use of tubing with internal diameters of either 0.8 or 1.5 mm has been reported to give improved precision over 0.5 mm without excessive decreases in dispersion. The terms  $D$ ,  $S_{1/2}$ , and  $P$  (see Table 1) have been used to describe the physical dispersion process and investigations have concluded that the most influential variables on dispersion were the length and internal diameter of the reaction coil. For single reagent chemistries the best results were achieved using at least twice as much reagent as sample, whilst keeping the total volume lower than half that required to give a dispersion of 2.

Whilst dispersion promotes chemistry between the reactants, and therefore sensitivity, it also causes dilution of the sample and subsequent loss of signal. Consequently it is important to optimize the reaction conditions and instrumental configuration to give the best analytical figures of merit for each application.

## Reaction Chemistry

One must not forget that the successful operation of SIA requires the judicious choice of detection chemistry. Although it may be possible to measure the analyte directly, typically the sample must be converted to a species compatible with the detection system. This is often a challenging, and sometimes daunting task, however, most common wet chemistry techniques such as colorimetric analysis and titration are easily adapted to SIA. As mentioned earlier, some methodologies and chemistries are unique to SIA, and are unable to be performed with other flow-based analytical techniques. Examples of such methods are the determination of factor XIII and the determination of morphine in nonaqueous process streams. The factor XIII assay requires the use of a complex series of reactions that are difficult to do manually, whilst the morphine sample is in a harsh organic matrix and is unable to be propelled through most pumping systems.

## Instrumentation

A typical SIA manifold is depicted schematically in Figure 2 and comprises a bidirectional pump, selection valve, reaction and holding coils, detector, and control software.

### Selection Valve

Central to the successful operation of an SIA instrument is a selection valve operated in synchronization with a pump, generally this valve is a multiposition valve, although auto samplers and magnetic snap valves have also been used for this purpose. The selection valve is connected to various sample and reagent reservoirs, typically via Teflon tubing.

### Propulsion Devices

It is imperative that the pumping device used in SIA is bidirectional and fully computer controllable. Initial reports of SIA utilized a sinusoidal pump, however, it was soon noted that 'any computer controllable piston pump capable of forward and reversed movement, would be suitable' and these were replaced with syringe pumps. Although the use of peristaltic pumps as propulsion devices for SIA was initially discounted due to the elasticity of the tubing, they can indeed be used and have the advantage of higher analytical throughput than syringe pumps. Recently the MilliGAT<sup>®</sup> pump has been designed specifically for use in FIA/SIA. These are self-priming positive displacement piston array pumps and do not contain syringes, check valves, or pulse dampeners. Alternate sources of fluid

propulsion, which have found limited utility are electroosmotic and gravity flow.

### Detectors

A large reason for the widespread utility of SIA is that any detection system that is capable of accepting a flowing stream may be utilized. It simply requires that the dimensions of the flow through cell be such that they allow solution propulsion with low-pressure pumps. Ideally detectors for SIA have a fast and stable response, high sensitivity, linearity of response over a wide range of analyte concentrations, low dead volume, low noise, do not fluctuate with temperature and flow rate, and are robust and relatively cheap. Unlike liquid chromatography and capillary electrophoresis, which can use nonspecific detection and rely on the resolving power of the separation, selectivity in SIA is achieved using prudent choice of reaction chemistries and detection parameters. Detection methods have included ultraviolet (UV)-visible, infrared, luminescence, and atomic spectroscopy along with electrochemical and turbidimetric measurements. Specific flow cell designs for sequential injection analysis include the 'fountain cell' and the 'jet ring cell'.

### Computer Control Software

In contrast to FIA where manual operation of pump and valve is easily achieved, the fundamental requirement for success in SIA is the accurate and precise synchronization of pumps, valves, and other hardware to obtain reproducible flow patterns. This, together with the benefits of electronic data acquisition and manipulation, necessitate the development of specialized software for overall instrument control. It has been noted that the lack of commercially available software was the most limiting factor in the development of SIA. In most cases specific 'in-house' programs have been developed to be compatible with the instrumentation available and software written in Turbo C++, Visual Basic, Basic, the Windows 95 environment, and LabVIEW<sup>®</sup> has been reported. Although recently commercially available software has become more widely available and the need to design purpose-built software has been lessened, some of this is instrument specific and many researchers choose to develop their own to suit the available components.

## Analytical Applications

SIA has been applied to the analysis of a wide variety of analytes in matrices as diverse as foods, beverages, bioprocesses, environmental, pharmaceutical, and

industrial processes. Published methods have incorporated sample treatment steps such as online dilution, preconcentration, separation on miniature columns, pH adjustment, phase transfer with membrane sampling devices, and immunoassay. Detection has been achieved using UV, visible and infrared spectrophotometry, turbidimetry, fluorescence, chemiluminescence, pH and ion selective electrodes, conductivity, and atomic spectroscopy, whilst some have employed chemometric manipulation of the resultant data. The following examples of analytical applications of SIA have been selected as they highlight the variety of sample treatment and detection options that can be incorporated into a method.

### Environmental Applications

The majority of analytical applications of SIA have involved the detection of analytes in environmental matrices. A considerable number of these methodologies have been concerned with the analysis of water samples, whilst some have been applied to soils, sediments, wastes, and plant materials. Applications have utilized molecular and atomic spectroscopy, fluorescence, radiochemistry, turbidimetry, and electrochemical detection techniques. Egorov and co-workers coupled chromatographic separation on a minicolumn with SIA for the determination of isotopes of americium, plutonium, and neptunium in vitrified nuclear wastes using inductively coupled plasma mass spectrometry (ICP-MS). Coupling of the ICP-MS detection system to the SIA was achieved using a four-port switching valve and ensured a continuous delivery of either the column eluate or aqueous nitric acid to the detector. The use of a confluence point (tee-piece) between the detector channel and a water reservoir has been reported to serve the same purpose when combining SIA with flame atomic absorption spectrophotometry.

### Food and Beverage Analysis

Spectroscopic, luminescence, turbidimetric, and electrochemical methods of detection have been combined with SIA for the successful determination of amino acids, sugars, and trace elements in matrices such as meats, vegetables, breads, wines, juices, and milks. Many of these methodologies required sample pretreatment and whilst most performed this in an offline manner there have been some reports of online sample cleanup. Microwave assisted digestion was performed in-line for the determination of phosphorous, calcium, magnesium, and iron in slurried foodstuffs, wine, milk, and soft drinks; whilst gaseous diffusion allowed interference removal for the determination of urea in milk.

### Industrial and Process Analysis

Industrial and processing solutions present some of the most challenging samples for analysis, as the matrices are typically complex and harsh. SIA has proved itself more than capable of such application and has been applied to the analysis of various analytes present in both industrial and fermentation processes. Determinations of a range analytes in industrial samples such as petroleum distillates, electroplating baths, mine process and effluent solutions, paper and pharmaceutical manufacturing have all been reported with SIA.

Wood pulp black liquors have been sampled directly from the processing vessel using SIA. The instrumentation automated the sample pretreatment and cleanup over an aluminum oxide minicolumn and then presented them to a high-performance liquid chromatography system for the determination of pyrocatechol, pyrogallol, gallic acid, and protocatechuic acid.

SIA instrumentation has also been modified to perform colorimetric titrations and one such apparatus has been applied to the determination of bromine number in petroleum distillates. Due to their organic nature, petroleum samples would not usually be able to be propelled through most pump tubings as they would be degraded. However, the use of SIA, which relies on reverse movement of the pump to aspirate the samples into a holding coil and via a selection valve, allows manipulation of such harsh matrices, as they never make contact with the propulsion device. The colorimetric titration system developed for bromine number assay utilized a reaction chamber fitted with an electrode for the *in situ* generation of bromine along with optical fibers for detection. Unfortunately interferences from sulfur-containing compounds resulted in errors when the method was applied to real samples.

### Bioprocess Monitoring

Several SIA applications have been reported for the determination of analytes such as ammonia, glucose, ethanol, lactic acid, and phosphate in a variety of fermentation media with spectrophotometric, turbidimetric, chemiluminescence, and electrochemical detection. This has included the indirect offline determination of glucose, lactic acid, and penicillin in *Penicillium chrysogenum* cultivars using chemiluminescence detection of enzymatically produced hydrogen peroxide. Whilst most SIA instrumental configurations consist of a single propulsion device, this system included a second pump for the injection of a reagent immediately prior to the detector.

The determination of D-lactic acid in *Lactobacillus delbrueckii* using SIA has been achieved with online sampling, filtration, dilution, and analysis based on the colorimetric detection of enzymatically formed NADH.

### Pharmaceutical Applications

The automation of certain pharmaceutical analyses through the utilization of SIA has received some interest within the research community. Applications to serial assays, drug dissolution testing, and drug screening have incorporated spectroscopic, electrochemical, and luminescence detection. Stopped flow SIA has been used to collect the chemiluminescence intensity versus time profiles of procaine, benzocaine, and tetracaine after their reaction with acidic potassium permanganate. The differing profiles were subsequently used to distinguish the analytes and resulted in reported detection limits as low as  $0.1 \mu\text{g ml}^{-1}$ .

SIA instrumentation has been applied to the automated dissolution studies of a sustained release formulation of ibuprofen. The instrument monitored the absorbance of seven replicate samples six times per hour. With the application of partial least squares regression analysis to the resultant absorbance data, this same instrumentation was capable of the simultaneous determination of aspirin, phenacetin, and caffeine in pharmaceutical formulations.

### Immunoassay

The manipulation of antigen–antibody interactions and subsequent detection of several analytes has been achieved using SIA. Whilst many of these applications have involved the use of SIA with bead injection (to be discussed later), some have used SIA for the direct analysis of cellular and bodily fluids.

Automation of a five-reagent procedure for the determination of factor 13, a chemistry that had only ever been performed manually, illustrates the potential of SIA for complex and difficult to perform chemistries. This methodology, reported by Guzman and Compton, uses a four-step sequence whereby factor 13 is activated by thrombin in the presence of calcium and UV radiation, the resultant activated product then mediates a condensation reaction between monodansylcadaverine and *N,N*-dimethylcasein to form a fluorescent product.

A specialized ‘fountain’ detection chamber equipped with an epifluorescence microscope was developed for live-cell studies of derivatized rat insulinoma cells. A coverslip coated with the cellular material was positioned in the chamber and SIA was

used to manipulate the type and rate at which fluid perfused the cells, whilst the resultant fluorescence was monitored. A comparison of this approach with corresponding FIA and fluid switching methodologies indicated that SIA was the most flexible and robust of the instrumentation tested.

### Renewable Microcolumns (Bead Injection)

Provided the instrumentation contains a suitable flow cell, small amounts of bead suspensions can be manipulated by SIA to form renewable microcolumns that act as disposable reaction surfaces, separation, and/or preconcentration devices. This involves the aspiration of a known volume of bead suspension followed by their trapping within a distinct geometry. The beads can then be perfused with carrier, sample, and/or reagents whereby the analyte is trapped on the surface of the beads and the appropriate chemistry is subsequently performed. Following detection, the beads are then discarded. Pollema and co-workers first reported this approach in 1992 when they trapped a solution of immunomagnetic beads within a magnetic field. A number of bead-trapping devices have been employed with the jet ring cell, porous frit, and rotating rod designs illustrated in **Figure 5**. This means of manipulating bead material for performing analysis has been applied to samples such as foods, beverages, urine, cellular material, and environmental and nuclear wastes.

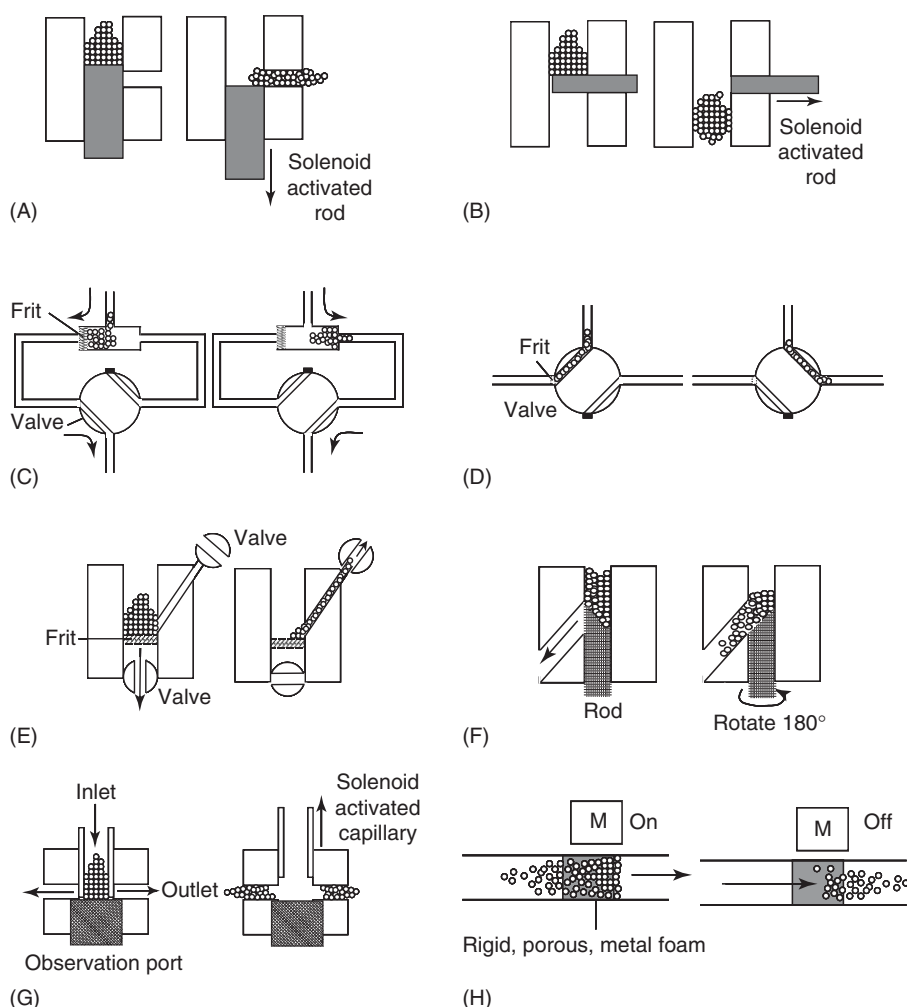

Electrically conductive glassy carbon beads have been manipulated with SIA to form renewable electrodes. The surface of the beads was coated with immobilized glucose oxidase and enabled the determination of glucose in beer and wine via the amperometric detection of hydrogen peroxide.

The utility of bead injection SIA for separation and preconcentration has been well demonstrated by the selective determination of strontium-90, americium-241, and technetium-99 along with various isotopes of plutonium and curium whose radionuclide activity was determined in nuclear waste samples using liquid scintillation counting.

### Sample Pretreatment and Preconcentration

Accurate determination of analytes in complex sample matrices is often problematic due to the presence of interferences, furthermore, analytes at low concentration may approach the detection limit of the method and consequently be unable to be directly determined. One of the great advantages of SIA is the ability to automatically preconcentrate samples from within various, and sometimes aggressive, solvents without risk of damage to the propulsion device.

**Figure 5** Schematic diagram representing some restriction devices that have been used for the formation of bead reactors. As published in *The Analyst*, 2002, 127, 997; reproduced by permission of the Royal Society of Chemistry.

After preconcentration, these samples can then be back-extracted into a similar solvent or into a matrix that is more compatible with the detection system. The use of SIA with bead injection was demonstrated for the preconcentration of nickel and bismuth on a cation-exchange resin prior to detection by electrothermal atomic absorption spectrometry (ETAAS) or ICP-MS.

Two liquid–liquid extraction steps were employed for the preconcentration and back-extraction of copper and lead prior to detection by ICP-MS. The analytes were complexed with ammonium pyrrolidine dithiocarbamate and extracted into isobutyl methyl ketone with the aid of a gravitational phase separator. As the ICP-MS is susceptible to organic solvents, a second liquid–liquid extraction whereby the analytes were displaced from the complex using Pd(II) and back-extracted into nitric acid was required.

### Introduction

In modern chemical analysis, high detection sensitivity is achieved by using specific physicochemical methods optimized for the task of trace analysis where the reported detection levels are often measured in  $\mu\text{g ml}^{-1}$  (ppm),  $\text{ng ml}^{-1}$  (ppb), or  $\text{pg ml}^{-1}$  (ppt). The achievement of such low detection levels may be possible primarily due to the use of modern analytical instruments equipped with new types of detectors, and also due to improved sample preparation methods. Both these factors are closely related to the purity of solvents used as mobile phases in different variants of liquid chromatography (LC), electrochromatography (EC), capillary zone electrophoresis (CZE), or as extraction medium in liquid-liquid extraction (LLE), solid-phase extraction (SPE), membrane separation (MSP), filtration (FT), flotation (FL), etc. Moreover, these high-purity solvents are also used as media to dilute the analyzed samples for chromatographic, spectroscopic, and electrochemical analysis. Thus, solvents used in chemical analysis must fulfill many physicochemical requirements.

Many of the high-purity solvents now available for techniques including LC, electromigration and/or membrane separation, as well as for spectroscopy. However, purification and quality testing of even commercial products is often necessary before use, particularly in the above-mentioned techniques that are applicable to multicomponent systems. For

instance, the mobile phases in LC, CZE, SPE, and MSP are often modified by different organic and/or inorganic salts, and may interfere with the target analyte. Organic synthesis also requires high-purity solvents or solvent mixtures with different composition. Synthetic products of high purity are used as reference materials for analysis.

In this article, the most important physicochemical properties of commonly used solvents are briefly reviewed, including methods for their purification, recovery, and quality testing.

### Solvents: Properties and Their Usage

In many cases, the proper sequence of molecular processes occurring in multistep multicomponent analysis systems depends strongly on the purity of the solvents used. Often, the quality of measured data can be improved by using solvents of suitably high purity. From the chromatographic or spectroscopic point of view, a good solvent should be characterized by high purity and, consequently, by lower values of transparency at low wavelength (ultraviolet (UV) cut-off) and for transparency of the desired analytical wavelength and refraction (refractive index). Also, parameters such as reactivity and good miscibility are important criteria for solvent selection. In LC investigations, multicomponent solvents (e.g., binary/ternary mixtures) that have low boiling points (between 20°C and 60°C) and low viscosity ( $\eta < 50 \text{ cP}$ ) are preferred. A good solvent should be able to dissolve the sample, although this is seldom a problem in analytical separations.

The important physical parameters of the most commonly used solvents are listed in **Table 1**.

**Table 1** Physicochemical properties of solvents used in various analytical techniques

<i>Solvent</i>	<i>Usage area</i>	$\varepsilon^{\circ}$ (on silica)	UV cut-off (nm)	RI at 25°C	$d_{25^{\circ}\text{C}}$ (g ml <sup>-1</sup> )	BP (°C)	$\eta$ at 25°C (cP)	$\varepsilon$ at 25°C

In extraction techniques (LLC, SPE, etc.), normal-phase liquid chromatography (NPLC), and thin-layer chromatography, aliphatic hydrocarbons (e.g., *n*-hexane, *n*-heptane) are usually used. The elution strength of these solvents is often modified by addition of more polar solvents. The fundamental problem with the eluents in NPLC is dissolved water and trace amounts of olefins. These contaminations can induce a change in the wavelength cut-off values (UV detection, spectrophotometry), baseline perturbation, and poor reproducibility of retention data. Halogenated solvents such as dichloromethane can react with some organic solvents (e.g., acetonitrile) to form crystalline products.

In reversed-phase liquid chromatography (RPLC) and electromigration techniques (CEC, CZE), aqueous solutions of methanol, acetonitrile, tetrahydrofuran, and dioxane are used as eluents. In this mode of LC, a fundamental concern is the purity of water, which can contain phenols, hydrocarbons, etc. Tetrahydrofuran is used frequently as the solvent in gel permeation chromatography. It must be stabilized by butylated hydroxytoluene used as antioxidant. Similarly, when halogenated solvents (e.g., trichloroethylene) are used triethanolamine is added as a

stabilizer. However, in ion-suppression and ion-pair RP-HPLC, the mobile phases are often modified by the addition of compounds that can change the dissociation constants of analytes such as inorganic and organic acids or ionic substances (e.g., ammonium chloride, cetyl chloride, etc.). The same situation occurs when buffers are used. All these components may contain inconvenient impurities that can crystallize (precipitate) and interfere in detection during the elution process. As a result of these impurities, extra peaks can appear in chromatograms, confusing the identification of the analyzed substances. The impurities can interfere with the analyte's retention even if a UV transparent mobile phase (e.g., methanol–water, acetonitrile–water, and/or ethanol–water) is used. As an example, the GC-FID chromatogram of analytical grade methanol is shown in **Figure 1**. This chromatogram illustrates that together with the main MeOH peak, trace impurities are also detected. Thanks to chromatographic methods it may be often used for the purity testing and QA/QC (quality assurance/quality control) of solvent manufacture.

Another factor that influences the separation process and may result from solvent impurities during

**Figure 1** Example GC-FID chromatogram of methanol for chromatographic analysis. Chromatographic conditions: column – Poraplot Q (25 m  $\times$  530  $\mu$ m  $\times$  20  $\mu$ m), temperature program – 70°C held for 3 min to 200°C at a rate of 8°C, carrier gas – helium (1.4 bar).

chromatographic elution is peak tailing and/or peak splitting. In SPE, the irreversible sorption of solvent impurities on the active sites of packing materials (e.g., surface silanols or chemically bonded ligands with polar groups such as  $-\text{OH}$ ,  $-\text{NH}_2$ ,  $-\text{CN}$ ) can be manifested by differences in the reproducibility of recoveries.

Therefore, before chromatographic or spectroscopic measurements are undertaken suitable preparation (e.g., isolation, purification, and preconcentration) of the sample is recommended. For this purpose, methods such as LLE, SPE, FT, and MSP are used. It should be noted that high-purity solvents are required to prepare analytical samples.

## Methods of Solvent Purification

Even though there are many methods for the purification of solvents, the most popular methods are based on distillation: simple, fractional, and steam distillation. In recent times, solvent purification on solid-phase packing materials is becoming popular, which can be carried out by LC, SPE, and ultrafiltration by the utilization of membranes.

### Distillation

Distillation is the oldest, easiest, and cheapest procedure for purification of solvents and is based on the application of Raoult's law. The physical foundations of this separation technique depend on the distribution of the constituents between the liquid and vapor phases being at the equilibrium. In general, the composition of the vapor is different from the composition of the distilled mixture, but azeotropic mixtures distil without changing its composition. However, during distillation of normal mixtures, the

principal component with lowest boiling point distils first and then the compounds with higher boiling temperatures. The effectiveness of distillation depends on the physical properties of the components in the mixture, the equipment used, and the method chosen.

Simple distillation refers to the process in which molecules transferred from the liquid phase to the vapor phase are not subjected to partial condensation or contact with the condensed liquid prior to reaching the vapor condenser. The composition of the vapor near the liquid phase does not change as it moves along the condenser. In this technique, equipment requirements are minimal, and, usually, a flask fitted with a condenser and a product receiver is sufficient.

Fractional distillation is used when a more efficient separation process than simple distillation is required. This type of distillation is an equilibrium process, in which the composition of the distillate is constantly changing as the distillation proceeds and is changing along the distillation column toward the outlet. The main element of the apparatus is the distillation column consisting of a series of plates located one over the other in a suitable tube that is placed under the receiver. Liquid evaporating from one (lower) plate condenses on the other (higher) plate, where the evaporation process is repeated. In each plate equilibrium between the liquid and the vapor is established.

The vapor, enriched with the more volatile component, flows upwards, whereas the condensed fluid enriched with the less volatile component flows downwards. The efficiency of the column is increased by increasing number of plates. By fractional distillation (**Figure 2**), it is possible to recover solvents of chromatographic grade, such as acetonitrile or methanol obtained from an azeotropic mixture of methanol–water or acetonitrile–water.

Steam distillation is a simple distillation procedure in which the vaporization of a mixture is achieved either by continuously blowing steam through a mixture or by boiling water and sample together. If sample contains both hydrophobic and hydrophilic components, two layers of distillate develop. In the typical steam distillation process, the two layers can be recovered separately. Aqueous distillation seems to provide the best compromise between time, cost and effort.

In many cases, satisfactory results are obtained when distillation is used for the purification of solvents. Normally, water used in HPLC investigations need not be purchased, but may be prepared by the user. A cheap and easy laboratory procedure for water purification is described below. Deionized

**Figure 2** Scheme of a fractional distillation system for organic solvent recovery: 1, cooler; 2, distillation column; 3, fraction flasks; 4, reboiler; 5, fraction split valve; 6, reflux valve; TIS, TIC, TIA – temperature sensors; FA – cooler sensor; LA – solvent level sensor. water with an added alkaline solution of  $\text{KMnO}_4$  is left standing for a few days, and then the solution is distilled twice in an apparatus made of hard glass. The conductivity of the water purified in this fashion may be as low as  $10^{-6} \text{ S m}^{-1}$ .

**Figure 3** Plots of absorbance data for mixtures of water and methanol at 254 nm versus the composition of the solution obtained using 3 cm quartz cuvette. Key: ○, methanol (analytical grade and water (home purified); ●, methanol (HPLC grade, J.T. Baker, Deventer, The Netherlands); and ▽, water and methanol (HPLC grade, J.T. Baker). In Figure 3, plots of absorbance for three combinations of water and methanol of various purity are shown. The main source of UV absorption of the binary mobile phase was evidently the impurities in methanol. A comparison of both the bottom curves shown in Figure 3 also proves the effectiveness of water purification by distillation.

Other solvents, such as aliphatic and aromatic hydrocarbons, alcohols, ethers, including tetrahydrofuran, halogenated solvent, can also be purified through distillation methods. However, in many cases the solvent impurities, water in aliphatic hydrocarbons, or halogenated solvents can make the distillation process less efficient. Therefore, in these cases more effective methods for purification of solvents are necessary.

### Adsorption Methods

In adsorption chromatography (NPLC), control of the water content in solvents is important. In some cases, it is preferred to mix known amounts of dry and water saturated solvents together in order to know or control the percentage of water saturation. On the other hand, addition of activated molecular sieve beads ( $4 \text{ \AA}$  or  $5 \text{ \AA}$ ) to the solvent storage bottle clearly improves their purity and reduces the water content. Impurities, in addition to water, can often be removed by adsorption methods, particularly frontal analysis, which is utilized often in LC.

According to this method, a glass column packed with small adsorbent particles (0.2–0.15 mm diameter), usually comprising dried silica gel or alumina oxide, is used (Figure 4).

The column, before being used for solvent purification, is heated at 473 K for 8 h under vacuum ( $10^{-3}$  Torr) to remove physically adsorbed water. After this operation, the unpurified solvent is injected into the column using a siphon-type injector. The purified solvent is collected in a solvent receiver equipped with a moisture trap.

Frequently, purification and stabilization of the mobile phase, during HPLC investigation, is carried out on precolumns, located between the solvent reservoirs and the injection valve. A precolumn situated

before the analytical column can serve to remove precipitate material when the sample is introduced into the eluent stream at the injector. SPE, a technique employing the principle of frontal analysis, is also used for solvent clean-up. It is mainly used for purifying small amounts of solvent, particularly, for sample dilution.

## Filtration and Membrane Techniques

Where impurities are present as microparticulate material filtration affords a convenient technique for solvent purification. The mobile phase containing added buffers or reagents may be filtered through a 0.5  $\mu\text{m}$  or smaller filter to remove particulate matter that can damage the analytical system. The equipment for filtration is simple. Usually, it consists of an Erlenmeyer flask connected to vacuum and a reservoir in which a porous filter disk or membrane is placed. The porous disk is usually made from nonporous spherical glass beads (1–2  $\mu\text{m}$ ) and/or polytetrafluoroethylene (PTFE). Membrane materials are usually made from PTFE, cellulose, or nylon. To improve the efficiency of the separation process, the surface of the filter disks or membrane surface are often modified chemically, similar to that used for chemically bonded packing materials in RP-HPLC and/or SPE. In this case, the surface properties (hydrophobic or hydrophilic) of filters and/or membranes determine the extent of purification possible.

Water may be satisfactorily purified using a compact water purification system that combines filtration, deionization, and charcoal treatment in a convenient, high-volume unit.

Ultrafiltration provides an alternative to filtration, where large molecules are separated from solution by employing membranes. Membranes are commercially available for separating molecules in the molecular weight range between  $10^3$  Da and  $10^6$  Da. Ultrafiltration is primarily used for isolation of low or high molecular weight substances from solvents. Figure 5 shows a comparison of the efficiency of acetonitrile purification using frontal analysis and the ultrafiltration technique.

Reverse osmosis is a technique similar to ultrafiltration, except that membranes of a much smaller pore diameter are employed, and the operating pressure is higher. The operating pressure must exceed the natural osmotic pressure. This technique has been applied to the purification of water and organic solvents.

In dialysis, solvents are purified by their ability to diffuse through membranes as a result of the

**Table 2** Concentration of water in solvent and difference in absorbance for the  $\lambda$  of the cut-off ( $\Delta A$ ) before ( $C_b$ ) and after ( $C_a$ ) purification

Solvent	$\Delta A$ (% v/v)	$C_b$ (mg l <sup>-1</sup> )	$C_a$ (mg l <sup>-1</sup> )
Acetonitrile A	69.7	2216.0	167.0
Acetonitrile B	10.2	297.0	143.0
Benzene	24.6	308.0	27.5
Cyclohexane	16.8	49.0	4.5
<i>n</i> -Heptane	21.3	18.8	7.7
<i>n</i> -Hexane	17.2	19.6	8.6
Methanol A	77.05	650.0	134.0
Methanol B	3.6	120.0	114.0
Tetrahydrofuran	61.3	1081.0	32.6
Toluene	23.1	167.0	10.0

concentration gradient. The overall efficiency of this process is controlled by the ratio of the flow rates and the properties of membrane, fluid channel, and local fluid velocity.

## Recovery and Quality Control

After purification, quality control of solvent purity is necessary. For this purpose, many different analytical methods are utilized. Generally, chromatographic methods such as GC, GC-MS, and HPLC are used. Moreover, UV, infrared, and nuclear magnetic resonance spectroscopy can also be applied but they tend to be less sensitive toward trace impurities. Water in organic solvents is usually determined by Karl-Fisher titration. On the basis of experimental data obtained before and after purification, the efficiency of the clean-up procedure is determined. In general, the efficiency of purification, e.g., the recovery, is expressed by the coefficient  $R$ . This parameter is defined as the ratio of the amount of impurities removed to the amount of solvent before purification:

$$R \pm \sigma = (V_a \pm \sigma_a)(V_b \pm \sigma_b) \times 100\% \text{ [v/v]} \quad [1]$$

or

$$R \pm \sigma = (C_a \pm \sigma_a)(C_b \pm \sigma_b) \times 100\% \text{ [v/v]} \quad [2]$$

where  $V_a$ ,  $C_a$  and  $V_b$ ,  $C_b$  denote volume or concentration of the removed impurities and solvent, respectively, and  $\sigma$ ,  $\sigma_a$ ,  $\sigma_b$  are individual standard deviations.

Table 2 summarizes the results for solvent purification by frontal analysis. In each case, purification improves their absorbance at the  $\lambda$  cut-off point ( $\Delta A$ ). The small improvement in the case of HPLC-grade methanol B is expected for this high-purity

solvent. The high level of impurity (absorbance difference,  $\Delta A = 77.5\%$ ) in analytical grade methanol A precludes its use in HPLC. Similarly, toluene, benzene, tetrahydrofuran, and acetonitrile A tested in the study cannot be used in HPLC without purification.

In spite of the high contribution and frequent use of commercially prepared solvents in laboratory practice, there is a need to apply these solvents with special care. In many cases it is indispensable to apply high-purity 'fresh' portions of solvents prepared in laboratory conditions (called home-made). The possibilities of using different techniques for the purification of solvents depend on laboratory equipment and technical requirements, so as to obtain a product with a purity that meets or even exceeds the guarantees provided by manufactures. Recovery values for purification of water, acetonitrile, alcohols, ketones, and aliphatic and aromatic hydrocarbons obtained by distillation methods are usually in the 97% to 99.92% range. By utilizing membrane techniques for solvent clean-up it is possible to obtain recoveries in a similar range ( $R$  from 97% to 99.90% (v/v)). In the case of halogenated solvents this range is very narrow (i.e., 98–99.80%). In every case one should remember that the factor having much influence on solvent quality (purity) is the storage of the pure solvent (including packaging materials). For this purpose containers of colored glass and with small volume, or nonreactive metal containers, which allow storing of the solvents in an inert gas atmosphere are recommended.

## Introduction

Electrochemical techniques in themselves do not give any direct structural information on adsorbates, attached thin films, or electrogenerated compounds. However, the introduction of spectroscopic monitoring of redox reactions within an electrochemical cell has led to vastly improved understanding of electrochemical reactions, especially complex follow-up reactions in solution. It has also offered insights into surface processes such as adsorption and surface reconstruction as well as the double-layer structure. The spectroelectrochemical dimension also introduces specificity when several species are present, and distinguishes Faradaic from non-Faradaic processes. The term spectroelectrochemistry generally refers to an *in situ* method for monitoring electrochemical redox processes and subsequent follow-up reactions. Direct spectroscopic monitoring of an electrochemically generated intermediate can help to identify

products. The spectra of the products can also be used to identify the site of the redox orbital. For example, the site of reduction of a metal complex can be located at a metal or a ligand orbital with the help of techniques such as ultraviolet (UV)–visible and electron paramagnetic resonance (EPR) spectroscopy. With increasingly complex multicentered complexes and organic molecules, as well as the advent of supramolecular chemistry, the location of the redox orbital involved in the electron transfer can often be determined by spectroelectrochemistry.

Regarding surface spectroelectrochemistry, the intense interest in the electrochemistry of single crystal surfaces, adatoms, oxide layers, and monolayers in the last decade has seen not only the enhancement of traditional methods (e.g., infrared (IR) and Raman microspectroscopy) but also the development of relatively new surface specific methods such as second-harmonic generation, sum-frequency generation, surface plasmon resonance (SPR), and surface-enhanced resonance spectroscopy (SERS). The increased access to synchrotron radiation has led to X-ray absorption and X-ray diffraction methods becoming more feasible as *in situ* techniques for thin films or species generated close to the electrode. In this article, for

## Introduction

Electrochemical techniques in themselves do not give any direct structural information on adsorbates, attached thin films, or electrogenerated compounds. However, the introduction of spectroscopic monitoring of redox reactions within an electrochemical cell has led to vastly improved understanding of electrochemical reactions, especially complex follow-up reactions in solution. It has also offered insights into surface processes such as adsorption and surface reconstruction as well as the double-layer structure. The spectroelectrochemical dimension also introduces specificity when several species are present, and distinguishes Faradaic from non-Faradaic processes. The term spectroelectrochemistry generally refers to an *in situ* method for monitoring electrochemical redox processes and subsequent follow-up reactions. Direct spectroscopic monitoring of an electrochemically generated intermediate can help to identify

products. The spectra of the products can also be used to identify the site of the redox orbital. For example, the site of reduction of a metal complex can be located at a metal or a ligand orbital with the help of techniques such as ultraviolet (UV)–visible and electron paramagnetic resonance (EPR) spectroscopy. With increasingly complex multicentered complexes and organic molecules, as well as the advent of supramolecular chemistry, the location of the redox orbital involved in the electron transfer can often be determined by spectroelectrochemistry.

Regarding surface spectroelectrochemistry, the intense interest in the electrochemistry of single crystal surfaces, adatoms, oxide layers, and monolayers in the last decade has seen not only the enhancement of traditional methods (e.g., infrared (IR) and Raman microspectroscopy) but also the development of relatively new surface specific methods such as second-harmonic generation, sum-frequency generation, surface plasmon resonance (SPR), and surface-enhanced resonance spectroscopy (SERS). The increased access to synchrotron radiation has led to X-ray absorption and X-ray diffraction methods becoming more feasible as *in situ* techniques for thin films or species generated close to the electrode. In this article, for

reasons of space, the emphasis has been placed largely on the *in situ* spectroscopy of solution species or electrogenerated species in a phase close to the electrode, such as in a thin film or polymer. These techniques are listed in Table 1. Omitted from this entry is a discussion of *ex situ* surface science measurements such as high-vacuum surface-specific spectroscopies: X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy, secondary ion mass spectrometry (SIMS), low-energy electron diffraction spectroscopy (LEEDS), high-resolution electron energy loss spectroscopy (HREELS). Other *in situ* measurements, such as gravimetry, impedance spectroscopy, and imaging techniques such as AFM and STM, have undergone spectacular growth over the last two decades, but do not yet involve radiation interacting with the electrode. But the coupling of many, if not all, spectroscopic probes to the scanning probe methods is certainly not far away. This will yield unprecedented imaging information. And, as with many other analytical techniques, spectroelectrochemistry is developing rapidly in response to better and less-expensive instrumentation and data handling, including the application of chemometric methods.

## UV-Visible Spectroscopy: Solution Species

The widespread use of the optically transparent thin-layer electrochemical (or OTTLE, Figure 1) cell led to the early growth in popularity of UV-vis spectroelectrochemistry. The OTTLE offers a way to measure both the redox potential ( $E^{0'}$ ) and the number of electrons transferred in the charge transfer process ( $n$ ) without requiring knowledge of the electron transfer kinetics, the diffusion coefficient, or, indeed, the concentration. A plot of the absorbance ratio versus potential ( $E$ ) should then be a straight line with a  $y$ -axis intercept giving  $E^{0'}$  and the slope giving  $n$ . OTTLEs have frequently been used in determining an accurate value for the redox potential,  $E^{0'}$ , of biological molecules with slow heterogeneous electron transfer rates. In these cases, a soluble redox mediator may be used to promote electron transfer in an indirect coulometric titration. OTTLEs are also used to study inorganic complexes with slow redox processes, for example, Cu(II) or Cu(I). Note that a great attraction of the technique is that neither the extinction coefficients nor the pathlength, or even the initial concentration are required as long as the limiting absorbances in each redox state (at sufficiently reducing and oxidizing potentials) can be measured.

The great advantage of the thin-layer design is that the small volume of analyte within the layer is

electrolyzed extremely rapidly, allowing the equilibrated spectrum to be recorded within seconds or minutes of applying the potential. The working electrode in these cells is usually a gauze, micromesh, or minigrid. Meshes of thickness as little as 5  $\mu\text{m}$  with up to 2000 lines per inch with 36% transmission are available. The thickness of the cell is determined by measuring the absorbance of a known compound and the volume by chronocoulometry. Typical values are 50  $\mu\text{m}$  and 0.09  $\text{cm}^3$ , with a characteristic time for complete electrolysis of 200 s for 2–4  $\text{mmol l}^{-1}$  solution. Such a cell would exhibit undistorted semiinfinite cyclic voltammograms (CVs) below  $\sim 20 \text{ mV s}^{-1}$  at concentrations less than 4  $\text{mmol l}^{-1}$ . Variable temperature cells generally have plenty of free volume to allow for expansion of the solvent and to prevent high pressures building up, leading to leaks.

The voltammetric response of the OTTLE cell should ideally be of the thin-film type with a peak separation close to zero and a symmetrical shape. The thin layer has restricted diffusion and exchange with the bulk solution, which leads to high uncompensated resistance and distorted responses at all but the lowest scan rates. OTTLE CV waves are often distorted with greater peak separations in the CVs than expected. Minimization of the  $iR$  (ohmic) drop is particularly applicable in the design of these thin-layer cells. Edge effects (i.e., diffusion to the edges that prevent the current in the cell reaching zero at long times – typically 1% residual current – is regarded as acceptable) can be minimized by limiting the optical area to a small central portion of the minigrid.

A thicker cell is possible if reticulated vitreous carbon (RVC) is used. For example, transmission of 13–45% for 100 p.p.i. (pores per inch) is possible for a 1.2–0.5 mm thick RVC plate. LIGAs are Lithographic-Galvanic structures that present some advantages over indium tin oxide (ITO) and metal meshes, namely improved stability, faster response times, and a greater range of electrode materials that can be used in the same cell. The electrodes are sandwiched between quartz rods coupled to the spectrometer using fiber optics.

For a sequential reaction without any branching pathways (such as decomposition of a reactive intermediate), one would expect to see isosbestic points in the thin-layer electrolysis. It is advisable to carry out several oxidation–reduction cycles to test the stability of the spectral responses; in other words, to see if the starting material is always fully regenerated.

Like all thin-film cells, the OTTLE cell is useful for studying the slow follow-up reactions of the electrogenerated species ( $>20$  s) since diffusion and

**Figure 1** (A) Traditional OTTLE cell. The minigrid is sandwiched between two microscope slides and the spacing is defined by Teflon tape. The three exposed edges are sealed with epoxy adhesive. (B) More robust, modern version using a commercial 0.5 mm UV cuvette and gauze.

convection effects do not interfere. But the relatively long time to achieve equilibration of the stagnant thin layer of the OTTLE or reflection cell does not allow one to study the kinetics of faster reactions. To overcome this, the forced convection regimes of the rotating disc electrode (RDE) and the channel-flow cell allow steady-state currents to be produced, which provides access to shorter time regimes. Both approaches have been investigated with optical detection of electrogenerated species. The rotating optically transparent electrode has been used mainly for photogeneration of species rather than spectroscopy. On the other hand, a rotating disk surrounded by an optically transparent, insulating ring has been constructed for the spectroscopic determination of intermediates. Alternatively, a light beam can be introduced by fiber optics near-normal to the RDE and reflected from the electrode. In the case of the channel flow cell the steady-state current is proportional to  $V^{1/3}$ , where  $V$  is the flow rate, and hence the absorbance should be given by  $i/V$ , i.e., proportional to  $V^{-1/3}$ . The absorbance also follows the Nernstian response of the current. For faster reactions still, chronoabsorptometry at an optically transparent electrode is used (see below).

### Chronoabsorptometry and Derivative Cyclic Voltabsorptometry

The technique of chronoabsorptometry, also known as potential step chronoamperospectrometry and

chronocoulopectrometry, monitors the time dependence of the absorbance. Here, the optically transparent electrode (OTE) is used in a thick-layer cell so that semiinfinite diffusion conditions prevail. Such cells generally use a gold or ITO (indium-doped tin oxide)-coated electrode. Recently, boron-doped diamond has shown great promise as a new electrode material, but its transparency has not yet been exploited in UV-vis spectroelectrochemistry. The absorbance of an electrogenerated species,  $R$ , at a wavelength where only  $R$  absorbs, increases with time ( $t$ ) as  $t^{1/2}$ . Unlike chronoamperometry, there is no need to determine the electrode area, or  $n$  (the number of electrons passed). The slope of the absorbance-time plot allows the determination of the (usually) unknown extinction coefficient  $\epsilon_R$  for the electrogenerated species, providing that  $c$  and  $D_O$  are known. No knowledge of the electrogenerated species' diffusion coefficient  $D_R$  is necessary. Usually, the concentration is known and it is a simple matter to determine  $D_O$  from a chronoamperometry, chronocoulometry, or ultramicroelectrode experiment. The chronoabsorptometric response has been used to determine the heterogeneous rate constant for electron transfer to biological redox centers. The advantage of the optical technique over conventional electrochemical methods is that the measurements can be made successfully in the presence of other Faradaic or charging processes.

Derivative cyclic voltabsorptometry (DCVA) is the optical analog of CV. Usually a fixed wavelength is

monitored while the potential is cycled (typically at scan rates up to  $50 \text{ mV s}^{-1}$ ). If several species are being monitored by DCVA it is important to remember that peak heights are proportional not only to concentration but also to the molar extinction coefficients, which in general are unknown. DCVA provides a way to remove the effects of Faradaic processes that do not involve the colored species of interest.

### **Near-Parallel Configuration: Long Optical Pathlength Thin-Layer Cell and Spatially Resolved Spectroelectrochemistry**

The optical pathlength in an OTTLE cell is short, giving low optical sensitivity. With the long optical pathlength thin-layer cell (LOPTLC), the light beam of the spectrometer passes parallel to the electrode surface, thereby sampling a greater pathlength (typically 1 cm) of the region immediately in front of the electrode (up to 0.5 mm). Enhancements of  $\sim 100$ -fold are observed due to the increased surface-area to volume ratio. Another advantage is that, as in reflection spectroscopy, there is no requirement for the electrode to be transparent. The electrode may be mounted vertically or horizontally, the former more practical for modern spectrometer slits. An unusual design uses a block of graphite or glassy carbon with a  $500 \mu\text{m}$  hole drilled through it. The cylindrical geometry facilitated the simulation of the time response. The LOPTLC is largely used in the same manner as the OTTLE (i.e., bulk electrolysis), but it is also possible to compute the time-dependent absorbance either analytically or numerically.

If spectra of surface adsorption or deposition processes are not desired in a study it may be worth considering a method in which the light beam passes parallel to the electrode surface such as LOPTLC or diffusion-layer imaging techniques. Grazing-angle laser reflection with  $5 \mu\text{m}$  resolution is useful for diffusion-layer imaging. However, to some extent, diffusion-layer imaging such as this has been eclipsed by the advent of electrochemical STM techniques.

Probe-beam deflection is a technique in which a monochromatic source, typically a He-Ne laser beam, passing parallel to the electrode surface, is used to monitor refractive index changes in the diffusion layer. It is a simple and cost-effective way of profiling the diffusion layer, and is used to monitor the diffusion layer ingress and egress of ions, particularly protons. It is often used in conjunction with electrochemical quartz crystal microbalance (EQCM) measurements that monitor mass changes within or on the electrode layer itself.

### **Other UV-Visible Techniques**

When monochromatic light is absorbed by an electrode surface, it will heat up imperceptibly leading to small temperature changes near the electrode. Such temperature changes can be monitored by photothermal or photoacoustic spectroscopy. In the former, a thermistor is attached to the back of the electrode. Alternatively, the temperature changes are monitored indirectly using either a piezoelectric ceramic detector attached to the electrode surface in order to monitor the dimensional changes occurring as a result of absorption, or by monitoring refractive index changes in the electrolyte (thermal probe beam deflection; similar to probe beam deflection above). If the light is modulated (chopped) at acoustic frequencies, sound waves will be generated near to the electrode that are then detected by a microphone (photoacoustic spectroscopy). Though useful for nonreflective or nontransmissive surfaces such as powders, these techniques have not found widespread use in electrochemistry, though it seems that photothermal spectroscopy with optical detection of the refractive index change is set for a comeback due to its ultrafast response and potential in IR microspectroscopy imaging.

If the electrode is a semiconductor, or if it forms a semiconducting oxide layer (e.g., Fe or Pb), light absorption may be directly monitored by photocurrent spectroscopy. Such photocurrents arise from minority carriers and are much larger than photoemission effects at metallic electrodes.

UV-vis methods are often combined with other techniques. For example, combined UV-vis and EPR spectroelectrochemistry was used in the study of anthraquinone reduction. But the EPR spectroelectrochemical cell design is demanding to implement successfully and the presence of the metal electrodes within the cell reduces sensitivity considerably (see later).

### **UV-Visible Spectroscopy of Surface Species: Specular Reflectance, Ellipsometry, Internal Reflection, and Waveguides**

Sometimes the desired electrode cannot be rendered transparent. Then, the spectroelectrochemistry of solution species may be performed using a reflective electrode (Figure 2). The results are, of course, identical to those in the transmission mode, except that the path length and hence the absorbance of dissolved species is increased by the factor  $(2/\cos \theta)$  where  $\theta$  is the angle of incidence (angle between the

beam and the normal to the electrode surface). Typically,  $\theta$  is  $\sim 45^\circ$  so as to avoid oversampling of the diffusion layer.

If large surface selectivity is required, it is necessary to consider the physics of the reflection process. Consider only the electric vector of the electromagnetic radiation and ignore the perpendicular magnetic

vector. For unpolarized light, the electric vector lies in all possible planes. Light with a component polarized perpendicular to the plane defined by the incident and reflected beams (the plane of reflection), i.e., parallel to the electrode, is termed the s-polarized component. Light polarized parallel to the plane of incidence is termed the p-polarized component. Both components will, in general, undergo different phase shifts and degrees of attenuation upon reflection, dependent on the angle of incidence and the refractive indices of the media.

The difference in phase, along with the ratio of the s- and p-polarized light intensities, is measured in the technique of ellipsometry, so called because the combination of two light vectors with a phase lag and unequal intensity, in general, leads to the electric vector tracing out an elliptical path in the direction of propagation (Figure 3A).

An ellipsometer (Figure 3B) measures the phase lag  $\Delta$  between the reflected s- and p-polarized light and the ratio of the extinction coefficients  $k_p$  and  $k_s$  ( $\tan \Psi = |k_p|/|k_s|$ ). The observed changes in intensity and phase as a result of the reflection at electrode surfaces depend on the refractive indices  $n_i$  of the various media,  $n = c/c_0 = (\epsilon\mu)^{1/2}$  where  $\epsilon$  is the dielectric constant and  $\mu$  the magnetic permeability, as well as on the absorbance of the media. The effect of the absorbance is often combined with the refractive index to yield a complex refractive index,  $\hat{n} = n - jk$  where  $k$  is the extinction coefficient. Similarly, a complex dielectric constant,  $\hat{\epsilon}$ , is given by  $\hat{n} = (\hat{\epsilon}\mu)^{1/2}$  with  $\hat{\epsilon} = \epsilon' - j\epsilon''$  where  $\epsilon' = (n^2 - k^2/\mu)$  and  $\epsilon'' = 2nk/\mu$ . Then, most optical materials are defined by three parameters  $\mu$ ,  $n$ , and  $k$ , or alternatively by  $\mu$ ,  $\epsilon'$ ,

**Figure 2** Reflection cell for solution/surface UV-vis or IR measurements. The body is fabricated from glass of Teflon. A similar cell is used in methods such as SHG. The cell may be vertically (avoids gas bubbles) or horizontally mounted. The light is delivered and collected by a reflection accessory or a fiber optic bundle. The working electrode may be mounted on a micrometer for greater control of the spacing between it and the window.

**Figure 3** (A) Diagram depicting the change from linearly to elliptically polarized light upon reflection at an electrode surface. (B) Schematic diagram of an ellipsometer setup.

and  $\epsilon''$ . Most reflectance and ellipsometry studies on growing surface coatings of thin films are modeled assuming the appearance of a third phase between the metal and the electrolyte due to the adsorbate, and the application of Fresnel's equations. The fitting of the data is carried out by computer. With two observed parameters the problem is underdetermined. In the past assumptions had to be made about the absorbance or the refractive index of the thin film, but nowadays the ratio of the intensity of the incident and reflected light is measured, or alternatively the angle of incidence and/or incident wavelength (spectroscopic ellipsometry) are varied, so removing any ambiguity about the refractive index of the new phase.

Due to its erstwhile greater speed in comparison to ellipsometry, specular reflectance using s- and p-polarized beams in the UV-vis region is a good method for studying surface adsorption and for rapidly determining the optical properties of substrates as a function of wavelength, with reflection changes of the order of  $10^{-5}$ – $10^{-6}$ . Unfortunately, in systems of electrochemical interest the reflectance changes are very small. To improve the situation, multiple reflections or glancing incidence are used together with chopping the light and phase-sensitive detection in order to measure absolute reflectivities. However, it is much easier to measure changes in reflectivity instead by using potential modulation (a small sinusoidal signal is superimposed) and phase-sensitive

detection in the technique known as electroreflectance, electrolyte electroreflectance, or potential-modulated reflection spectroscopy. Electrochemists were surprised to find very large changes in the apparent reflectance of noble metals using this method even in the absence of adsorption. This was traced to the modulating potential-induced motions of the free electrons in a layer 0.1 nm thick near the surface, giving it very different optical characteristics to the bulk. Under conditions in which this 'third phase' is forming the reflectance changes linearly with the amount of adsorbate or new phase, and it is found that the s-polarized beam intensity is half the p-intensity at  $\theta = 45^\circ$ . Electroreflectance can be very sensitive to surface layers; for example, in monitoring the production of adsorbed CO on single-crystal electrodes used to model fuel cell reactions.

An alternative reflection setup makes use of single (or multiple) internal reflection within an OTE (Figure 4). However, at each internal reflection, a small portion of the intensity 'leaks out' (it is correctly known as an evanescent wave) into the thin film electrode layer and beyond into the solution and can be used to detect any absorbing species. The method is also known as attenuated total reflection (ATR). The evanescent wave intensity decays exponentially as  $\exp(-\delta/x)$  with distance  $x$  from the interface. The penetration depth,  $\delta$ , depends on the wavelength and the optical properties of the substrate, electrode film, and solution:  $\delta = \lambda/(4\mu \text{ Im } \xi)$

**Figure 4** (A) (Top) Otto ATR configuration; (middle) reflection-absorption; (bottom) Kretschmann ATR configurations. (B) Electrochemical cell for thin film SPR spectroscopy using the Kretschmann configuration. where  $\text{Im } \xi$  is the imaginary part of  $(\hat{n}_3 - n_1^2 \sin^2 \theta_1)^{1/2}$  where  $\hat{n}_3$  is the complex refractive index of the solution,  $n_1$  is the index of refraction of the substrate, and  $\theta_1$  is the angle of incidence within the substrate. Typically,  $\delta$  is the order of a quarter of a wavelength, 50–200 nm for UV–vis light. Usually, the absorption is small and so this is a very good technique for highly absorbing solutions. In other situations, the sensitivity is too low and multiple internal reflections are required. It is a useful technique for the determination of the rates of very fast, second-order follow-up reactions, since these will cause rapid loss of colored electrogenerated species before it has diffused very far from the electrode. Perhaps, however, the greatest advantage of ATR over other IR methods is its ability to sample only small path-lengths of strongly IR-absorbing solvent. Recent studies have looked at the potential of optical waveguides as internal reflection elements. Although the sensitivity is enormously increased due to the increased light intensity, by their very nature waveguides are limited to monochromatic probe wavelengths.

Reflection spectroscopy has also been carried out successfully by reflection off a water/immiscible liquid interface. Total internal reflection at a liquid–liquid interface can be used to monitor ion-transfer across the interface. For example, the kinetics of the reduction of TCNQ and the oxidation of 1,1'-dimethylferrocene by  $[\text{Fe}(\text{CN})_6]^{3-}$  in the aqueous phase have been considered. The kinetics of these reactions were studied by chronoabsorptometry, assuming diffusion control. Ion-transfer kinetics across interfaces have been treated theoretically and applied to the study of indicator transfer.

## Surface Plasmon Resonance

At a particular combination of refractive indices and incident angles an incident beam may come into resonance with the surface plasmons due to electron motion in the electrode. The minimum in the intensity (SPR minimum) is located precisely by varying the angle of incidence over a small range. Commercially available instruments generally employ the Kretschmann configuration as described above for ATR (Figure 4). The prism serves to fulfill the SPR condition in terms of refractive index and incident angle. The SPR minimum is observed over a very narrow range of incident angles (1–2°) and its shape and angular position are very sensitive to the optical constants and hence the presence of absorbates. Either the refractive index can be measured, or assuming a model for the monolayer, the extent of

coverage or thickness of the adsorbed layer can be determined. Other forms of spectroscopy such as luminescence or light-scattering are possible using SPR. Usually, a He–Ne laser is used and the angle is varied (though fixed angle, varying wavelength mode is also used). Alternatively, to eliminate the need for moving parts, a wedge of laser light is delivered to the surface and the reflected light is monitored using an area charge-coupled device (CCD) detector, as in some commercial instruments for bioassays. Unlike SERS, SPR uses a thin gold film as substrate or electrode because this offers far greater reproducibility than the roughened SERS electrode. It has been successfully used in monitoring the adsorption of biological molecules, self-assembled monolayers and double-layer structure. Greater versatility is obtained if gold films deposited on microscope slides are pressed against the prism. Waveguides prepared using multilayers on the substrate can be used to amplify the effect. The surface can be imaged by diverging the laser beam and detecting using a CCD detector. Very small refractive index changes can be measured, such as those caused by an electric field gradient within a thin film. SPR spectroscopy gives complementary information to EQCM measurements and the two techniques have been combined effectively. Despite its attractions, SPR places some restrictions on the electrode, but greater flexibility is possible using the Otto configuration (Figure 4).

## Second Harmonic Generation

When an intense light beam is directed to a noncentrosymmetric crystal then light may be reflected not only at the incident frequency,  $\omega$ , but also at the second harmonic frequency  $2\omega$ . Such second harmonic generation (SHG) is an example of nonlinear behavior, and is the basis for optical components such as frequency doublers. Since a surface or interface is inherently noncentrosymmetric, light from the electrode–liquid interface may show evidence for SHG (Figure 5). The intensity of the SHG light is dependent on the square of the incident intensity, and also on the square of the second-order nonlinear optical susceptibility, which in turn depends on the asymmetry of the interface. The effect is both angle and wavelength dependent. Although the effect is weak, typically  $10^{-12}\%$  of the incident intensity, requiring pulsed laser excitation and gated detection methods, the fact that the  $2\omega$  signal can only arise from the surface region lends the technique the advantage of surface specificity and blindness to the bulk solution. The  $2\omega$  signal intensity is sensitive to the presence of absorbed species and, in particular,

**Figure 5** Schematic SHG setup. Key: BS = beamsplitter, L/2 = half-wave plate, P = polarizer, L = lens, F = filter, MC = monochromator, PMT = photomultiplier tube, GI = gated integrator, DA = data acquisition, PD = photodiodes. (Reprinted with permission from Marrucci L, Paparo D, Cerrone G, *et al.* (2002) *Optics and Lasers in Engineering* 37: 601–610. © 2002, with permission from Elsevier.). The cell generally uses a reflection cell similar to that in **Figure 2** with a Dove prism (**Figure 4A** (middle)).

the rearrangement of adsorbed molecules (e.g., CO) or ions on the single-crystal electrode surfaces. It is also not particularly demanding of the nature of the metallic electrode (in contrast to SERS or SPR) and so metals such as platinum or mercury can be used. Furthermore, since the excitation source is visible light, less light is absorbed by the solvent and so longer path length cells can be used. In addition to simply measuring the intensity of the SHG beam as a function of potential or time, it is possible to derive molecular orientation information from the polarization dependence of the intensity, and symmetry information (if different from the surface) by rotating the sample or plane of polarization about the surface normal.

### Vibrational Spectroelectrochemistry: Fourier Transform Infrared Raman, and Sum Frequency Generation

Vibrational spectroelectrochemical techniques, particularly Fourier transform infrared (FTIR), with the advent of less-expensive and more sensitive spectrometers, have enjoyed a great increase in popularity over the last few years. The advantages over UV–vis spectroscopy include greater specificity and enhanced information content. An IR OTTE transmission cell with IR-transparent windows can be built by modifying a commercial liquid cell. Raman spectroscopy is also very easily carried out with an OTTE cell, but a flow cell is more useful for SERS studies of adsorption, since the solution can be replaced without disturbing the optical alignment.

Another popular configuration for FTIR is the reflectance geometry, which is clearly necessary when the electrode cannot be rendered transparent or the focus of interest is not the solution electrogenerated species but thin films growing on the surface of the electrode itself. A retractable electrode allows operation under both thin layer (15  $\mu\text{m}$ , 1 s electrolysis time) and semiinfinite conditions (**Figure 2**). An external reflection accessory is required to deliver the light to the electrode surface. This geometry is also used for Raman spectroelectrochemistry. Since solvent absorption is a usually major problem (though much less so for water solvent using Raman spectroscopy) the electrode is usually capable of close approach to the window surface in order to minimize the absorption due to the electrolyte. In early IR studies of surface processes the IR beam was monochromatic and the potential stepped between a background (where no Faradaic processes are occurring) and the working potential. This is called potential modulated or electrochemically modulated infrared spectroscopy (EMIRS). Alternatively, at fixed potential, the polarization of the beam can be modulated between s- and p-polarizations (polarization-modulated infrared reflection–absorption spectroscopy (PM-IRRAS) or simply (IRRAS). As mentioned above for the visible region, the s-polarized and p-polarized beams undergo different phase changes and attenuation on reflection. The signal is plotted as  $\Delta R/R = (I_p - I_s)/(I_p + I_s)$ . It turns out also that in the IR region the s-polarized light undergoes a phase lag on reflection  $\sim 180^\circ$ , leading to destructive interference between the incident and reflected beams. This means that there is a greater intensity of p-polarized light available for absorption by molecules and thus only vibrations with a dipole moment change perpendicular to the electrode are selected. This is the ‘surface-selection rule’, and operates in addition to the usual IR selection rule. Of course, since the solution is isotropic, no differential signal is observed from solution species.

PM-IRRAS can be implemented using modern commercially available FTIR spectrometers. Indeed, most modern surface IR studies simply use these instruments in conjunction with some form of subtraction. In subtractively normalized FTIR or potential difference IR, a single beam FTIR spectrum  $S_r$  is collected at a reference potential  $E_r$  (at which no Faradaic processes occur) and then at successively higher or lower potentials  $E_s$  scans  $S_s$  are obtained. Then plots (usually overlaid) of  $\Delta R/R = (S_s - S_r)/S_r$  are obtained for a range of working potentials. Unlike EMIRS or PM-IRRAS, there is no necessity for the electrode process under study to be reversible. The method is very popular, capable of investigating

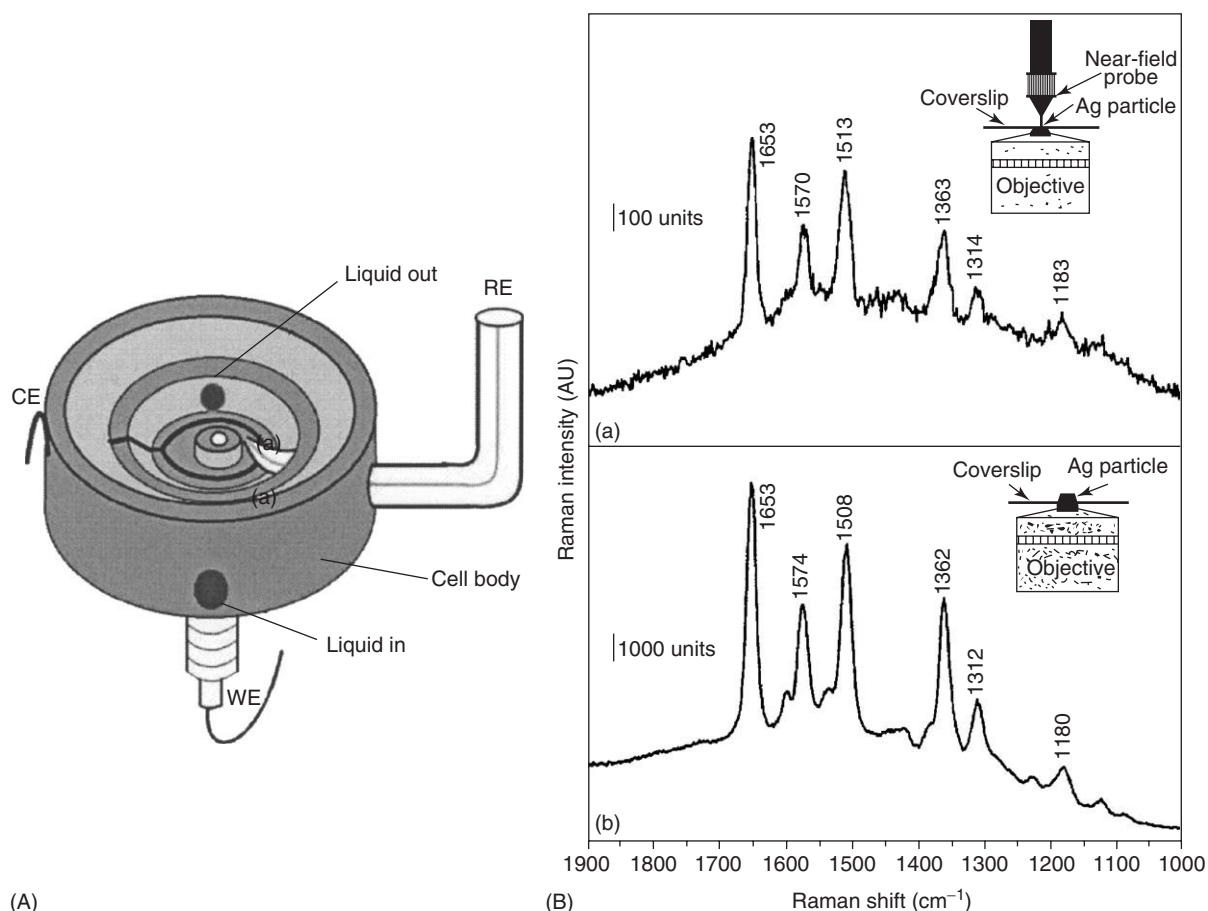

a wide range of electrode materials, but in contrast to the other methods it does not give absolute spectra and suffers from incomplete subtraction of strong absorbance bands due to solvent and electrolyte entering and leaving the thin-layer region. Often thin-layer cells must be used to reduce solvent absorption, and these introduce additional problems such as resistance effects and rapid electrolysis of solutes within the thin layer. If a thin film of gold or silver is evaporated onto the surface to provide islands for adsorption, it is possible to observe surface-enhanced IR absorption from adsorbates. This effect is closely related to the more familiar SERS effect in Raman spectroscopy.

In order to minimize the influence of strong solvent absorption, the IR beam can be internally reflected within an OTE, as for UV-vis internal reflection or ATR described above. The difference is the necessity for an IR-transparent OTE, preferably with a high refractive index, such as Si, Ge, or KRS-5 coated by a thin film electrode, typically gold or Pt. As explained above for the UV-vis version of this method, the penetration depth is related to the crystal refractive index, and is typically of the order of 1  $\mu\text{m}$  for IR radiation. This means that signals from the adsorbate, solute, and solvent are of comparable magnitude, and so the solvent is more easily subtracted. Also, there is no need for a thin layer configuration so mass transport is improved. Multiple internal reflections can be used to maximize the signal, and, as in external reflection, the potential may be modulated, or co-addition of several FTIR scans at working and background potentials may be used to improve the sensitivity. The technique obviously suffers from a lack of versatility in the choice of electrode substrate but the Otto configuration, in which the electrode is brought up to the uncoated crystal, may overcome this constraint.

The normal Raman effect is very weak: as little as  $10^{-12}$  of the incident intensity appears as Raman scattering. Although usually a scan is produced as in FTIR, Raman spectra may also be obtained at fixed wavenumber for time-dependent studies, with coaddition of large number of scans obtained by stepping between two potentials and allowing time for equilibration between cycles. The final signal is analyzed in a similar way to chronocoulometric techniques. This, of course, requires a reversible system. If more than one wavelength needs to be monitored then instruments are available with optical multichannel analyzer detection. The Raman signal can be very much greater if resonance enhancement or surface enhancement (SERS) is exploited. SERS, in particular, at a roughened Ag or Au electrode can lead to an enhancement of  $10^5$ – $10^6$ . The electrode is roughened

by a series of 'oxidation–reduction' cycles designed to produce surface features with nanometer dimensions. The enhancement arises from two separate effects: (1) the electromagnetic effect, whereby the nanometer structures concentrate the electric field through surface plasmon waves; (2) the chemical effect, i.e., chemisorption of the molecule on the surface gives rise to a new electronic state and a resonance Raman effect. The mechanisms can be distinguished somewhat by looking for evidence of chemisorption (band and intensity shifts on adsorption) and the excitation wavelength and potential dependences of the signal. Both mechanisms only operate over a short range from the surface, and in both cases SERS spectra give additional information on molecular orientation by application of the surface selection rules. Recently, it has been discovered that a SERS-active surface or colloid is far from homogeneous in response and that only particles of a certain size on the surface ('hot spots') deliver very high Raman intensities (enhanced by a factor of  $\sim 10^{14}$ ). This has led to several reports of single molecule spectra at colloids for molecules using surface-enhancement Resonance Raman spectroscopy. It remains to be seen whether this can be achieved routinely on electrode surfaces, perhaps with the help of scanning tip technology. SERS suffers from a time-dependence and lack of reproducibility, which makes quantitative applications difficult. There have been some successful attempts in recent years to prepare reproducible SERS surfaces by using, for example, monodisperse metal nanoparticles or by depositing metal films over latex nanospheres. Two other drawbacks are that SERS cannot be used on single-crystal electrodes, and that the effect is limited to the coinage metals, some of which make poor electrode materials. However, it has been shown that pinhole-free thin film of 3–30 atomic layers of other metals (e.g., Pt, Rh) do not reduce the SERS effect from the underlying silver layer by too much (factor of  $\sim 4$ – $5$ ). Two advantages of Raman over IR are that the laser light is hardly scattered at all by water as solvent and that low-frequency bands are readily observed.

Confocal Raman microspectroscopy is now yielding spectra at micrometer spatial (lateral) resolution, and can be carried out *in situ* (Figure 6). Diffusion profiles can also be mapped. The potential for FTIR microspectroscopy is also apparent, and results have been obtained that are superior to those from OTTE cells, with simpler cell design, thanks to the use of microelectrodes. But the discrimination against solvent absorption is poor for *in situ* work; it is hoped that higher intensity sources, such as synchrotron sources, in conjunction with PM-IR-RAS, can overcome this problem.

By analogy with SHG described above, if two light beams of fixed visible frequency  $\omega_{\text{vis}}$  and tunable IR frequency  $\omega_{\text{ir}}$  are focused onto a surface then due to nonlinear optical effects reflected light of sum-frequency  $\omega_{\text{sf}} = \omega_{\text{vis}} + \omega_{\text{ir}}$  may be detected, hence the name sum-frequency generation. The selection rules demand that only bands that are *both* IR and Raman active are observed. Unfortunately, sum frequency generation (SFG) suffers from the disadvantage of strong IR absorption by solvent, so irradiation from the back of the electrode is sometimes used.

## Electron Paramagnetic Resonance and Nuclear Magnetic Resonance

Electron paramagnetic resonance (EPR) has played a very important role in the study of electrogenerated intermediates, particularly of radical cations and anions of organic compounds. The *g*-values and the

hyperfine coupling constants help to identify the radical and the redox orbital. The obvious difficulty of *in situ* EPR, in which the radicals are generated at the electrode placed within the microwave cavity, is the presence of metal electrodes and the high dielectric constant solvents typically used in electrochemistry. These absorb microwaves, reducing the microwave intensity in the cavity. The electrodes also disrupt the resonant frequency of the cavity, leading to difficulties in tuning the cavity and requiring precise cell positioning. To avoid these difficulties, the cell is sometimes placed outside the cavity (external generation), particularly if very low temperatures are required to obtain meaningful EPR signals of some metal species. The external generation can be a conventional cell or an inline flow cell, for which detailed and reproducible mass transport characteristics are known. Nevertheless, many *in situ* EPR electrochemical cell designs have been published with the rectangular cell and mesh working electrode

flow cell proving most popular, due to its higher working electrode area and thus higher sensitivity. The flow cell allows ready replacement of the solution without having to retune the cavity, and also provides improved mass transport. Kinetic studies require modeling of the lifetime of the signal as a function of flow rate. Bubble formation is also suppressed if the solution enters from the bottom. The reference electrode is placed as close to the working electrode as possible, but outside the cavity, and the auxiliary electrode is placed downstream from the cavity. Even so, the mass transport characteristics of the cell are far from ideal and distorted CVs are inevitable. However, the signal can be correlated with the charge passed (recommended, since EPR is very sensitive to impurity signals, a notable example being  $\text{ClO}_2^\bullet$  from perchlorate oxidation). The line-widths of stable radicals can give information on their concentration and environment (freely tumbling dilute radicals give narrower lines). The line-width can be used to measure the self-exchange rate. Very unstable radicals can be trapped using a spin trap to give a more stable radical adduct whose spectrum can be observed at leisure.

The much lower sensitivity of nuclear magnetic resonance (NMR) and the need for higher fields and a spinning sample have thwarted many attempts at *in situ* electrolysis. However, metallized glass electrodes can be designed with low 'skin depth', i.e., the thickness of metal required to reduce the RF fields to  $1/e$  of its value. A recent practical cell uses a normal spinning 10 mm NMR tube into which dips a stationary electrode assembly suspended above the probe. If spinning can be avoided, then the stationary probes of solid-state NMR machines can be used. For example, this method has allowed the study of surface species on catalytic metal powder electrodes, e.g., the adsorption of CO from methanol on high-surface-area Pt particles. The use of NMR pulsed field gradient methods has been widely used for the study of ionic diffusion in electrolytes, such as polymer electrolytes for Li batteries, in the absence of electrode materials.

## X-Ray Absorption Spectroscopy (XAS)

X-rays are strongly scattered by matter with a cubic dependence on wavelength. Superimposed on the scattering spectrum, obtained in transmission mode, are small step-like features (absorption edges) due to absorption by X-rays at wavelengths sufficient to eject a core electron from the atom. The precise wavelength is related to the ionization energy and is thus element specific. As in light absorption, the

absorbance is defined from  $I = I_0 \exp(-\mu x)$  where  $\mu$  is the absorption coefficient at the particular wavelength and  $x$  is the distance into the material. In the spectrum  $\mu$  is plotted against the X-ray energy and the scattering curve is subtracted. Buried in the leading edge of the absorption ('near-edge') are absorptions due to excitation of electrons from the core to higher atomic orbitals. These low-intensity bands are called fine structure; hence, the terms X-ray absorption near edge structure or, alternatively, near-edge X-ray absorption fine structure. This can be analyzed to give information on the oxidation state and ligand environment. At higher energy than the absorption edge, more fine structure (extended X-ray absorption fine structure) is observed, associated with the interference patterns generated between ejected electron waves and recently other waves scattered back from surrounding atoms. This can be processed to give information on the local environment of the absorbing atom, and is very useful for amorphous materials and even solution species. Due to strong scattering from solvent molecules, and the low concentration of surface species or thin films, the best results have been obtained using thin-layer transmission cells ( $\sim 10 \mu\text{m}$  thick) and high-intensity sources, such as a monochromated synchrotron source, covering a wide range of wavelengths are required. Cells use polymer windows (such as Mylar or polythene) and thin-film electrodes on polymer substrates, metal foils, or gauzes (Figure 7A). The electrodes and electrolyte can even be placed in a plastic bag or pouch. As an alternative to transmission mode, the cell can be held at  $45^\circ$  to the beam and the detector picks up the X-ray fluorescence emitted at all angles from the recombination of atoms and electrons (and hence closely related to the absorbance). X-ray fluorescence detection is more sensitive. Using similar electrochemical cells, X-ray standing wave spectroscopy can be used to give information on electrode double-layer structure or polymer coatings.

## X-Ray Diffraction and Surface X-Ray Scattering Methods

Structural information on electrodes can also be obtained as a function of potential by X-ray using monochromatic synchrotron radiation and similar transmission cells to those used for XAS (Figure 7B). Transmission cells (Laue mode) are best suited to adsorbates, while reflection (Bragg) cells are used for thicker films. Laboratory rotating anode sources can also be used, and here the instrument usually demands a reflection cell geometry. Stable systems such as solid-state cells and batteries give better

**Figure 7** (A) Cell for transmission XAS (Reprinted with permission from Soderholm L, Antonio MR, Williams C, and Wasserman CR (1999) *Analytical Chemistry* 71: 4622–4628. © 1999, American Chemical Society.) (B) Cell for X-ray scattering (GIXD). (Reprinted with permission from Kondo T, Tamura K, Takahasi M, Mizuki J, and Uosaki K (2002) *Electrochimica Acta* 47: 3075–3080; © Elsevier.) Similar cells have been used for surface XAS.

stability over the long periods required for data collection, since these sources are  $10^3$ – $10^5$  times less intense than synchrotron sources. For surface thin films, i.e., surface X-ray scattering (SXS), greater selectivity over the bulk is achieved using grazing incidence X-ray scattering, also known as grazing-incidence diffraction. SXS, though technically very demanding, has yielded spectacular results on single crystal electrode surface reconstruction and underpotential deposition. Information from both the reflected beam (emerging at the angle of incidence in the plane of reflection) and the scattered beams (other directions) are used. The former gives information on the roughness of the surface while the latter gives information on the surface structure. This can be combined with XAS data using the same cell configuration.

## Mass Spectrometry

Traditionally, products and adsorbates had to be volatile enough so that they could be carried from the cell into the mass spectrometer, either by headspace sampling, or, more commonly for near-simultaneous analysis (referred to as differential electrochemical mass spectrometry), across a nanoporous, gas-permeable membrane (e.g., Teflon) supported at the tip of a microcapillary placed close to the electrode. Alternatively, a Pt-coated membrane electrode can be used. But the advent of the so-called ‘soft’ atmospheric pressure desorption/ionization techniques associated with liquid chromatography–mass spectrometry has allowed the sampling of the solvent and involatile solutes directly. The spectra are more

interpretable as there is less fragmentation, and hence fewer lines not due to molecular ions. These techniques include atmospheric pressure chemical ionization, which uses a corona discharge, thermospray mass spectrometry (probe at  $290^\circ\text{C}$ ), particle beam (e.g., fast atom bombardment, FAB), and electrospray mass spectrometry (probe at high voltage). The sampling may be done using a membrane-coated capillary inlet in the electrochemical cell or by placing a flow cell immediately before the spectrometer (Figure 8). The time between electrogeneration and detection, the ‘dead time’ is 0.5–1 s, depending on the electrochemical cell’s conversion efficiency, flow rate, and ionization method. The best performance is usually seen for the thermospray systems, permitting simultaneous mass CVs to be recorded at scan rates of  $1$ – $10\text{ mV s}^{-1}$ . Electrospray ionization is of particular interest for the study of charged, electrogenerated inorganic species, but it is less useful for organic species that are not easily oxidized or protonated/deprotonated. It has long been suspected that the high voltage used in the electrospray process inadvertently causes electrochemical oxidation of neutral solutes at the tip. In order to enhance this oxidation for less readily oxidized organic analytes, a working electrode has been placed at the electrospray tip to apply an impressed potential.

## Other Methods

Cells have been designed to monitor insertion electrodes by Mössbauer spectroscopy. The technique is limited to relatively few nuclei. But these include

**Figure 8** Setup for electrochemical thermospray MS. (Reprinted with permission from Regino M, Weston C, and Brajter-Toth A (1998) *Analytica Chimica Acta* 369: 253–262; © Elsevier.)

$^{57}\text{Fe}$ , and hence Mössbauer spectroscopy finds uses in corrosion studies, although enrichment of the iron is sometimes required. The electrode must be very stable as a single spectrum can take several hours or days (depending on film thickness), so its use has been restricted largely to solid-state or battery systems. The sample must be thin enough to prevent the absorption or scattering of the  $\gamma$ -rays. In contrast to XRD methods Mössbauer spectroscopy offers local structural information on the iron or tin centers in mixed oxides. Finally, neutron reflectivity spectroelectrochemistry has proven useful for the investigation of electrode coatings. It could be regarded as the neutron equivalent of ellipsometry, with the advantage of much higher spatial resolution.

## Introduction

Ultraviolet-visible (UV-visible) spectrophotometry is primarily a quantitative analytical technique concerned with the absorption of near-UV (180–390 nm) or visible (390–780 nm) radiation by chemical species in solution. These regions of the electromagnetic spectrum (see **Table 1**) provide energy that gives rise to electronic transitions. The various colors of visible light and the complementary colors of solutions absorbing at particular wavelengths are shown in **Table 2**. Because of the superimposition of vibrational and rotational transitions the UV-visible spectrum of analytes in solution shows little fine structure. For this reason the technique is not commonly used for identification (although all molecules will have a wavelength of maximum absorption) but is one of the most widely used for quantitative analysis. Under

controlled experimental conditions the amount of radiation absorbed can be directly related to the concentration of the analyte in solution (Beer's law; see below). It can be used to quantify both organic (primarily in the near-UV) and inorganic (primarily in the visible) species.

## Spectra-Structure Relationships

In general, organic compounds absorb energy in the near-UV region due to  $\sigma \rightarrow \sigma^*$ ,  $n \rightarrow \sigma^*$ ,  $n \rightarrow \pi^*$ , and  $\pi \rightarrow \pi^*$  transitions. Most transitions of interest involve the

**Table 2** The visible spectrum

<i>Wavelength (nm)</i>	<i>Color absorbed</i>	<i>Color observed</i>
390–420	Violet	Green–yellow
420–440	Violet–blue	Yellow
440–470	Blue	Orange
470–500	Blue–green	Red
500–520	Green	Purple
520–550	Yellow–green	Violet
550–580	Yellow	Violet–blue
580–620	Orange	Blue
620–680	Red	Blue–green
680–780	Purple	Green

**Table 1** The electromagnetic spectrum

<i>Region</i>	<i>Wavelength range (m)</i>	<i>Wavelength range (commonly used units)</i>	<i>Type of transition</i>
$\gamma$ -Ray	$< 10^{-12}$	$< 1$ pm	Nuclear
X-ray	$10^{-12}$ – $10^{-8}$	0.001–10 nm	Inner shell electron
Far-ultraviolet	$10^{-8}$ – $1.8 \times 10^{-7}$	10–180 nm	Middle shell electron
Near-ultraviolet	$1.8 \times 10^{-7}$ – $3.9 \times 10^{-7}$	180–390 nm	Outer shell electron
Visible	$3.9 \times 10^{-7}$ – $7.8 \times 10^{-7}$	390–780 nm	Outer shell electron
Near-infrared	$7.8 \times 10^{-7}$ – $2.5 \times 10^{-6}$	0.78–2.5 $\mu$ m	Molecular vibration
Mid- and far-infrared	$2.5 \times 10^{-6}$ – $10^{-3}$	2.5–1000 $\mu$ m	Molecular vibration and rotation
Microwave	$10^{-3}$ –0.3	0.1–30 cm	Molecular rotation
Radio wave	$> 0.3$	$> 30$ cm	Electron and nuclear spin

promotion of  $n$  or  $\pi$  electrons to the  $\pi^*$  excited state and therefore involve molecules containing delocalized  $\pi$  electrons, i.e., aromatic and conjugated aliphatic species. The functional groups in these molecules that absorb energy are known as chromophores. The wavelength of maximum absorption of a molecule can be altered by the nature of the substituent(s) on the aromatic ring or the conjugated system. Substituents containing lone pairs of electrons, e.g.,  $-\text{OH}$ ,  $-\text{NH}_2$ , generally result in a longer wavelength of maximum absorption and a higher molar absorptivity of the molecule. Such groups are known as auxochromes.

Some inorganic compounds can be detected in the visible region by their inherent absorption of radiation. For example, the transition metal ions and their complexes are often colored and have a reasonable molar absorptivity due to transitions involving the 3d and 4d orbitals; lanthanoid and actinoid ions have characteristically sharp absorbance peaks due to effective screening of their 4f and 5f orbitals, respectively. Inherently nonabsorbing inorganic species can often be determined by a selective derivatization reaction wherein the non-absorbing analyte is reacted with an appropriate reagent to form an absorbing complex. Derivatizing reagents can be either universal (such as dithizone (diphenylcarbazone), PAR (4-(2-pyridylazo)resorcinol), and PAN (1-(2-pyridylazo)-2-naphthol) or selective for a particular species under appropriate reaction conditions (such as 1,10-phenanthroline for iron(II) and 1,5-diphenylcarbazide for chromium(VI)).

## Quantitative Aspects

The relationship between absorbance and concentration is known as Beer's law (also referred to by other names such as the Beer–Lambert law and the Bouguer–Lambert–Beer law) and is defined by the equation:

$$A = \epsilon bc$$

where  $A$  is the absorbance of the solution (no units),  $\epsilon$  is the molar absorptivity (units of  $\text{l mol}^{-1} \text{cm}^{-1}$ ),  $b$  is the path length of radiation through the absorbing medium (units of cm), and  $c$  is the concentration (units of  $\text{mol l}^{-1}$ ).

Beer's law can be derived as follows using the nomenclature shown in Figure 1. The transmittance ( $T$ ) is defined as the ratio ( $I/I_0$ ) and therefore

$$\%T = 100(I/I_0)$$

Absorbance ( $A$ ) is defined as  $\log_{10} I_0/I$ , which is the same as  $-\log T$ . Consider a thin layer of solution  $dx$ .

**Figure 1** Attenuation of radiation by an absorbing sample solution.

The decrease in power ( $dI$ ) across  $dx$  will be  $-\alpha I c dx$ , which can be arranged to give  $dI/I = \alpha c dx$ , where  $\alpha$  is a proportionality constant. Integrating over the path length of the cuvette gives

$$\int_{I_0}^I -dI/I = \alpha c \int_0^b dx$$

which gives

$$-\ln(I) - (-\ln(I_0)) = \alpha bc$$

which rearranges to give

$$\ln(I_0/I) = \alpha cb$$

Converting to  $\log_{10}$  gives

$$\log(I_0/I) = abc$$

which is the same as

$$A = abc$$

wherein  $a$  is another proportionality constant. Substituting concentration units of  $\text{mol l}^{-1}$  gives

$$A = \epsilon bc$$

Beer's law can also be applied to multicomponent systems by utilizing the additive effect of absorbances in solution. For example, two components (1 and 2) in a mixture can be quantified by measuring the absorbance at two wavelengths ( $x$  and  $y$ ) and knowing the molar absorptivities of 1 and 2 at the two wavelengths ( $\epsilon_x$  and  $\epsilon_y$ ) as follows:

$$A_x = \epsilon_{1x}bc_1 + \epsilon_{2x}bc_2$$

$$A_y = \epsilon_{1y}bc_1 + \epsilon_{2y}bc_2$$

The unknown concentration  $c_1$  and  $c_2$  can be determined by solving the simultaneous equations above.

More complex mixtures can be analyzed in a similar way providing that there are no deviations from Beer's law. Derivative spectrophotometry can also be used to mathematically process the data after acquisition in order to improve spectral resolution in multi-component systems. In this approach the zero-order spectrum is derivatized to give first order ( $dA/d\lambda$ ) or higher plots of the rate of change of absorbance against absorbance.

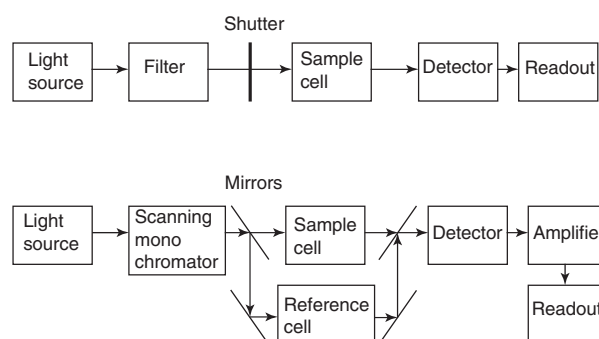

Beer's law is not valid at high concentrations ( $>0.01 \text{ mol l}^{-1}$ ) due to interactions between analyte molecules. There are also apparent limitations to the applicability of Beer's law due to instrumental and chemical deviations. Major instrumental deviations result from the fact that radiation impinging on the sample is polychromatic rather than monochromatic and the effect of stray radiation. Other, less important, instrumental factors are reflection losses, path length variability, light scattering and fluorescence (in the sample cell), and nonideal behavior in the signal processing and readout devices. Chemical deviations relate primarily to changes in absorbance due to changes in the chemical environment of the sample, e.g., pH. A classical example of this is the pH-dependent absorbance of Cr(VI) in solution due to the equilibrium between chromate (yellow) and dichromate (orange):

Other important equilibria that affect absorbance involve acid–base forms of a species (such as pH indicators) and metal–ion complexes. With all equilibria there will be one wavelength, known as the isosbestic point, where the absorbances of both species are equal because they have the same  $\epsilon$  value. The nature of the solvent (and the sample cell) and refractive index changes can also cause a positive deviation and this should be checked as part of the measurement protocol for the blank.

## Instrumentation

The basic instrumentation consists of a radiation source, a wavelength-selection device, a sample compartment, a detector, and an output device. For visible radiation a tungsten filament is the most common source and for near-UV radiation a deuterium lamp is usually used. Light emitting diodes can also be used as low cost sources with narrow bandwidths (typically 20–30 nm). For the best resolution a grating monochromator is used as the wavelength-selection device (this can also be used for scanning the range of interest); for lower-cost, lower-resolution systems a filter is used. The sample compartment is usually a cell with

**Figure 2** Block diagrams of single-beam (above) and double-beam (below) spectrophotometers.

a 1 cm square cross-section made of quartz (for the near-UV), glass, or plastic (for the visible). Consideration should also be given to the absorption characteristics of the solvent when developing a quantitative method. For detection a photomultiplier is the standard device but phototubes and, increasingly, photodiodes and diode arrays are also used.

The two most common optical configurations for UV–visible spectrophotometers are single-beam and double-beam arrangements (see **Figure 2**). Single-beam instruments are usually cheaper whereas double-beam instrument are more convenient for spectral scanning. An alternative optical arrangement is used in diode array spectrophotometry, wherein polychromatic light from the source passes through the sample cell and is then dispersed by a grating onto a linear diode array detector.

## Applications

UV–visible spectrophotometry is principally used for the quantitative determination of organic and inorganic constituents in a wide range of sample matrices, e.g., environmental, biochemical, pharmaceutical, clinical, and food. The technique can be used for the direct determination of absorbing species, such as the determination of nitrate in water at 208 nm, but care must be taken to avoid matrix interferences. Reaction rate measurements, used in methods based on catalytic reactions, can overcome such interferences and provide enhanced sensitivity. The technique can also be used for indirect determinations following derivatization of the analyte with a selective reagent to form an absorbing species, e.g., the determination of Fe(II) in water at 510 nm after reaction with the bidentate ligand 1,10-phenanthroline.

Systems based on diffuse reflectance from solid surfaces rather than absorbance in solution are also commercially available, particularly for clinical analysis, and fiber optic sensors based on spectrophotometric principles have been developed for

clinical and environmental applications. Spectrophotometry is also used extensively in combination with separation techniques such as liquid chromatography and capillary electrophoresis as a generic detector, as it is in nonchromatographic flow systems such as flow injection analysis.

### Definition and General Considerations

Diode array spectrometry represents a particular approach for characterizing the result of the interaction between electromagnetic radiation and the sample, based on simultaneous measurement of light intensity over small spectral intervals having equal width. This is achieved through the following sequential stages, as schematically shown in **Figures 1** and **2D**:

1. interaction between the polychromatic beam and the sample;
2. spatial dispersion of the transmitted (eventually reflected or emitted) radiation according to wavelength by means of a fixed optical element;
3. imaging the dispersed radiation in a flat focal plane; and
4. simultaneous sampling of the dispersed radiation interval using photosensitive detectors, precisely positioned in the flat focal plane.

Each of the detectors measures the radiation intensity on a spectral width resulting from a division of the linearly dispersed wavelength interval by the number of photosensitive receivers disposed side to side. Alternatively, diode array spectrometry can be employed, which supposes a transformation of the continuum into discrete values, generally followed by interpolation and smoothing procedures.

This approach is essentially different from the other alternatives for characterizing polychromatic radiation. **Figure 2A** illustrates the basic principle of a conventional scanning spectrometer. The

polychromatic radiation produced by the source is incident on an optical device called monochromator through an entrance slit. Dispersion is achieved with a moving optical element (prism, plane, or concave diffraction grating) focusing at a time through the exit slit a specific wavelength related to the incident angle ( $\theta$ ). This wavelength passes through the sample, and the transmitted intensity is measured by a unique detector. Spectrum reconstitution is achieved sequentially by scanning the wavelength interval in question.

The Hadamard multiplexing technique (**Figure 2B**) is also based on the dispersion of the transmitted radiation by the sample with a fixed optical element (identical to the diode array approach), while detection is carried out by means of a unique large bandpass detector. Mask displacement allows simultaneous intensity measurement on multiple spectral channels at different times. Spectrum reconstitution is achieved by solving the system of mathematical equation generated by the mask movement in time.

The Fourier multiplexing technique (**Figure 2C**) is based on the interferometric process applied to the incident beam. For a given position of the moving mirror inducing different pathway lengths, constructive interference is obtained only for a series of specific wavelengths. The detector generates a periodic function  $I = f(t)$ , analyzed by means of a Fourier series. Then, the resulting sinusoidal or cosinusoidal pure functions are recombined to generate an intrinsic  $I = f(\lambda)$  dependence.

It is thus obvious that diode array spectrometry can be differentiated from the other spectrometric techniques by the following considerations:

1. the use of a polychromator placed after the passage of the incident beam through the sample;

clinical and environmental applications. Spectrophotometry is also used extensively in combination with separation techniques such as liquid chromatography and capillary electrophoresis as a generic detector, as it is in nonchromatographic flow systems such as flow injection analysis.

### Definition and General Considerations

Diode array spectrometry represents a particular approach for characterizing the result of the interaction between electromagnetic radiation and the sample, based on simultaneous measurement of light intensity over small spectral intervals having equal width. This is achieved through the following sequential stages, as schematically shown in **Figures 1** and **2D**:

1. interaction between the polychromatic beam and the sample;
2. spatial dispersion of the transmitted (eventually reflected or emitted) radiation according to wavelength by means of a fixed optical element;
3. imaging the dispersed radiation in a flat focal plane; and
4. simultaneous sampling of the dispersed radiation interval using photosensitive detectors, precisely positioned in the flat focal plane.

Each of the detectors measures the radiation intensity on a spectral width resulting from a division of the linearly dispersed wavelength interval by the number of photosensitive receivers disposed side to side. Alternatively, diode array spectrometry can be employed, which supposes a transformation of the continuum into discrete values, generally followed by interpolation and smoothing procedures.

This approach is essentially different from the other alternatives for characterizing polychromatic radiation. **Figure 2A** illustrates the basic principle of a conventional scanning spectrometer. The

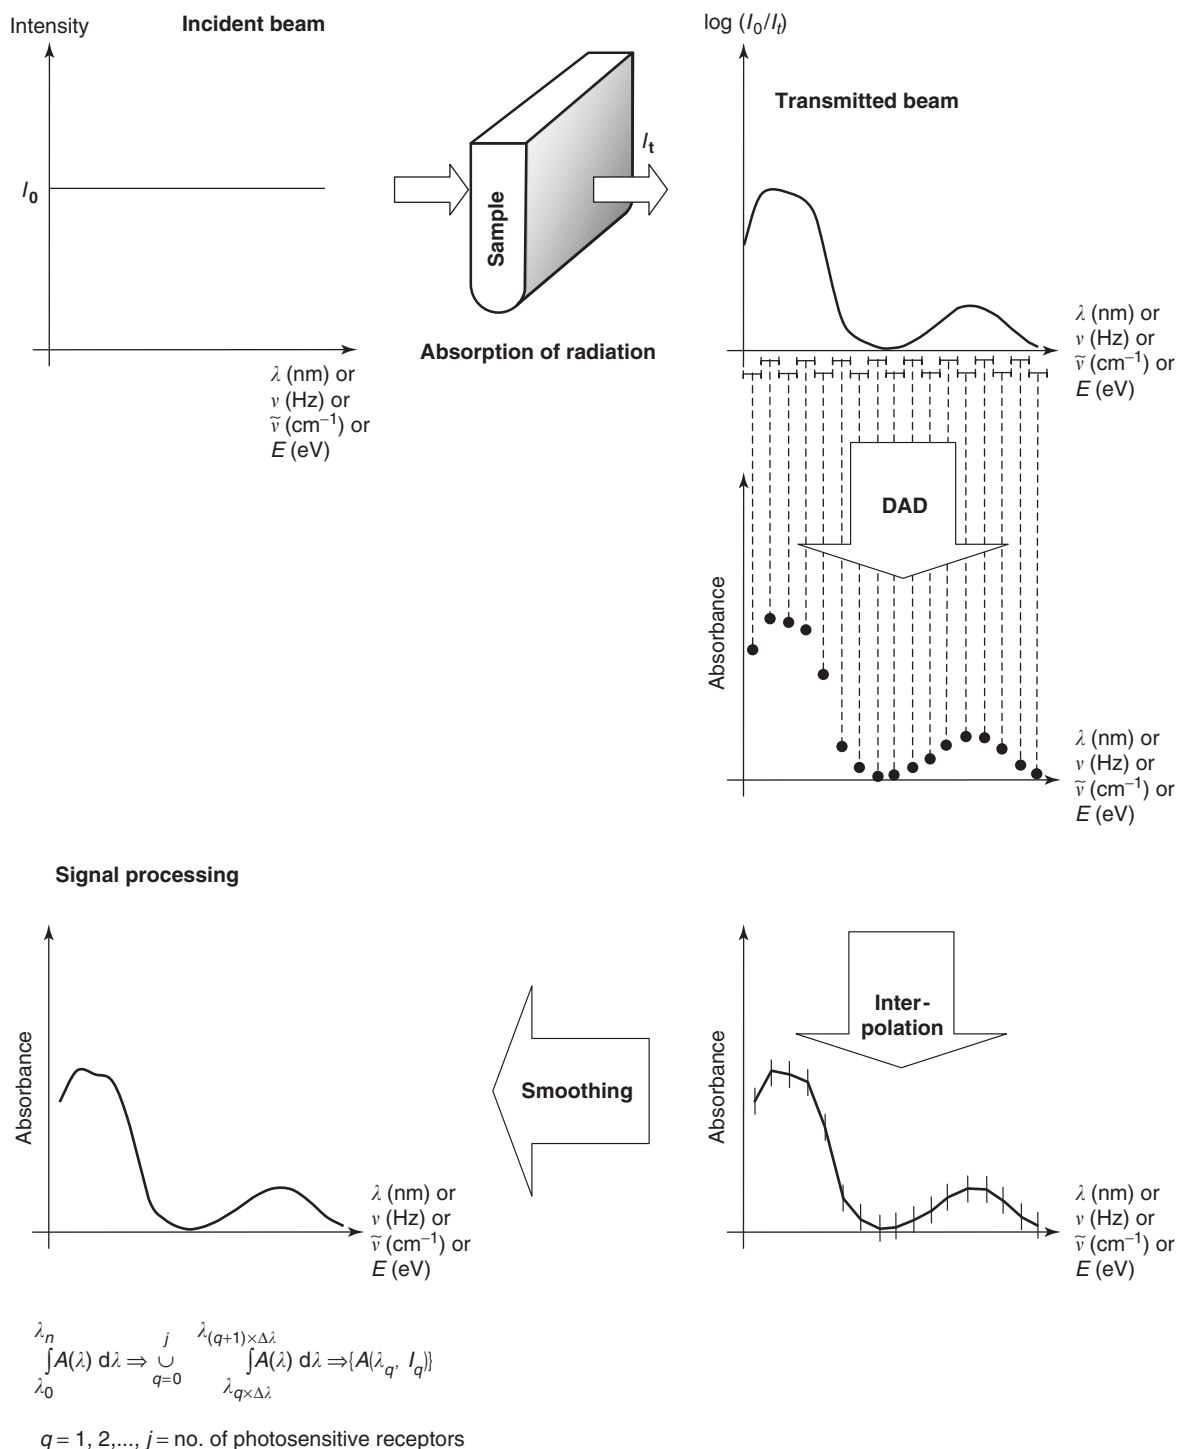

polychromatic radiation produced by the source is incident on an optical device called monochromator through an entrance slit. Dispersion is achieved with a moving optical element (prism, plane, or concave diffraction grating) focusing at a time through the exit slit a specific wavelength related to the incident angle ( $\theta$ ). This wavelength passes through the sample, and the transmitted intensity is measured by a unique detector. Spectrum reconstitution is achieved sequentially by scanning the wavelength interval in question.

The Hadamard multiplexing technique (**Figure 2B**) is also based on the dispersion of the transmitted radiation by the sample with a fixed optical element (identical to the diode array approach), while detection is carried out by means of a unique large bandpass detector. Mask displacement allows simultaneous intensity measurement on multiple spectral channels at different times. Spectrum reconstitution is achieved by solving the system of mathematical equation generated by the mask movement in time.

The Fourier multiplexing technique (**Figure 2C**) is based on the interferometric process applied to the incident beam. For a given position of the moving mirror inducing different pathway lengths, constructive interference is obtained only for a series of specific wavelengths. The detector generates a periodic function  $I = f(t)$ , analyzed by means of a Fourier series. Then, the resulting sinusoidal or cosinusoidal pure functions are recombined to generate an intrinsic  $I = f(\lambda)$  dependence.

It is thus obvious that diode array spectrometry can be differentiated from the other spectrometric techniques by the following considerations:

1. the use of a polychromator placed after the passage of the incident beam through the sample;

**Figure 1** Basic principle of diode array spectrometry.

- the use of a polychromator that disperses light according to wavelength by means of a fixed optical element (holographic concave diffraction grating) and subsequent imaging of the dispersed light in a flat focal plane;
- the use of photosensitive detectors serially placed in the flat focal plane, generating simultaneous intensity readouts over a given spectral width; and
- spectrum reconstitution based on the correlation of the reading generated by each detector

**Figure 2** Comparative overview on different instrumentation principles used in molecular absorption spectrometry.

according to the position assigned to a dispersed wavelength.

## Concave Diffraction Gratings

The concave diffraction grating is an optical element combining two functions: (1) reflecting and focusing

light in a flat path (given its concave geometry) and (2) dispersing light according to wavelength (given its groove pattern). It consists of finely spaced lines produced on the concave face of a spherical surface.

Concave diffraction gratings were first introduced in spectrometric practice by Henry Rowland in 1883. Based on Fermat's principle, Rowland was able to

specify the shape and location of the grating lines, without having all technological facilities for producing them. According to Rowland, an aberration-free image can be produced for a given wavelength if the geometry of the grooves on the grating concave surface follows the intersection of a family of hyperbolae. The modern theory of the concave holographic diffraction gratings (the term holographic refers to the production technology of the grating) was proposed by Namioko *et al.*

As shown in Figure 3, the incident polychromatic light is focused on the concave diffracting grating by means of an entrance slit positioned on the Rowland circle, giving also the radius of curvature of the grating ( $R$ ). The length of the incident light beam is  $L_I$  and  $\alpha$  is the corresponding angle measured against the normal to the diffraction grating surface at the center.  $\beta_i$  are diffraction angles for wavelengths included in the specified spectral interval (from  $\lambda_0$  to  $\lambda_n$ ). The concave grating focuses the dispersed light in a flat focal (spectral) plane. All distances from the grating surface to the focal plane are denoted as  $L_i$  ( $i=0, \dots, n$ ) the index corresponding to the wavelength.  $L_H$  is the length of the diffracted wavelength ( $\lambda_H$ ) falling perpendicularly on the focal plane. The focal plane makes an angle  $\gamma$  with the normal to the last diffracted wavelength. Other

notations are as follows:  $N$  is the groove frequency at the center of the grating (number of grooves per millimeter);  $M$  the diffraction order;  $d$  the groove spacing at the center of the grating (nanometers); and  $\lambda_F$  the wavelength used during holographic grating fabrication.

The following equations describe the imaging in the plane of dispersion produced by a concave diffraction grating:

- the grating equation

$$\sin \alpha + \sin \beta_i = m \times N \times \lambda_i; \quad N = \frac{10^6}{d}$$

- the tangential (spectral plane) focus equation

$$\frac{\cos^2 \alpha}{L_I} - \frac{\cos \alpha}{R} + \frac{\cos^2 \beta \times \lambda_i}{L_i} - \frac{\cos \beta}{R} - \frac{m \times \lambda_i}{\lambda_F} \times C_f = 0,$$

$$i = 0, \dots, n$$

- the sagittal (astigmatic) focus equation

$$\frac{1}{L_I} - \frac{\cos \alpha}{R} + \frac{1}{L_i} - \frac{\cos \beta_i}{R} - \frac{m \times \lambda_i}{\lambda_F} \times C_a = 0,$$

$$i = 0, \dots, n$$

**Figure 3** Basic principles of the concave diffraction grating.

- the coma equation

$$\frac{\sin \alpha}{L_i} \left( \frac{\cos^2 \alpha}{L_i} - \frac{\cos \alpha}{R} \right) + \frac{\sin \beta_i}{L_i} \left( \frac{\cos^2 \beta_i}{L_i} - \frac{\cos \beta_i}{R} \right) - \frac{m \times \lambda_i}{\lambda_F} \times C_c = 0, \quad i = 0, \dots, n$$

where  $C_f$ ,  $C_a$ , and  $C_c$  are constants depending on the experimental setup used during the production of the holographic concave diffraction grating.

The optical properties of a concave grating can be expressed as follows:

1. Angular dispersion – representing the angular separation between two wavelengths. The angular dispersion is calculated using the relationship

$$\frac{d\beta_i}{d\lambda_i} = (m \times N \times 10^{-6}) / \cos \beta_i$$

2. Linear dispersion – defined as the segment across the focal plane on which the spectral interval is spread out (generally expressed in nm/mm). The linear dispersion is given by the formula

$$\frac{d\lambda_i}{dx} = (10^6 \times \cos \beta \cos \gamma) / (m \times N \times L_i)$$

At the wavelength normal to the focal plane, the previous relation should be rewritten as

$$\frac{d\lambda_H}{dx} = (10^6 \times \cos \beta \cos^2 \gamma) / (m \times N \times L_H)$$

3. Wavelengths and diffraction orders – for a grating of given groove density and for given values of  $\alpha$  and  $\beta$ ,

$$m \times \lambda = \text{constant}$$

so that if the diffraction order  $m$  is doubled,  $\lambda$  is halved, and so on.

4. Resolving power – defined as the ability of the concave diffraction grating to separate adjacent spectral lines. Two consecutive wavelengths are resolved if their separation (considered as a distance) is such that the maximum of the first one falls at the starting minimum of the second (the Rayleigh criterion). It is demonstrated that the resolving power, RP, is given by the relation

$$RP = \frac{\lambda}{d\lambda} = m \times N \times W = m \times G$$

where  $W$  is the illuminated width of the grating and  $G$  represents the total number of grooves on the grating surface.

The resolving power of a grating depends on its width, the central wavelength to be resolved, and the geometry of the optical instrument.

## Manufacturing of Concave Diffraction Gratings

The mechanical ruling method for manufacturing concave diffraction gratings has been used since the late 1960s. Although A. Cotton in 1901 produced experimental interference gratings, even before the launch of the holography theory by Gabor, the availability of ion lasers and grainless photosensitive materials (photoresists) was lacking until the mid-1960s.

The interference produced by two coherent, equally polarized monochromatic optical waves of identical intensity, intersecting each other, generates a combined intensity distribution of fringes (bright and dark lines). Fringes are recorded on photosensitive plates with concave geometry. The light intensity varies sinusoidally with position, as the interference pattern is scanned along a direction. By modifying the intensity ratio between interfering sources, the exposure can be controlled. The separation between two adjacent maxima is  $d = \lambda_F / (2 \sin \varphi)$  ( $\lambda_F$  is the wavelength of the monochromatic sources and  $\varphi$  is the half-angle between the interfering beams).

If the wavefronts have spherical section and are converging or diverging, the interference pattern produced will represent confocal hyperboloids (ellipsoids are obtained if one wavefront diverges while the other converges). Addition of auxiliary concave mirrors or lenses into the paths of the interfering beams can render the fringe pattern toroidal. The former situations lead to first and, respectively, second generation concave holographic gratings.

The recording process is schematically given in **Figure 4**. According to the manufacturing process parameters ( $\lambda_F$ ,  $\delta$ ,  $\phi$ ,  $D_1$ , and  $D_2$ ), one can control the constructive constants of the grating ( $C_c$ ,  $C_a$ , and  $C_f$ ).

It is worth noting that the groove profile resulting from holographic manufacture is sinusoidal, while mechanical ruling generates triangular profiles. Consequently, holographic gratings produce different efficiencies for a given wavelength and spectral order with respect to ruled gratings. Holographic gratings for the visible and ultraviolet (UV) spectral ranges exhibit less stray light and ‘ghost’ spectra than do classically ruled ones, because they have less random and systematic imperfections.

On recording the pattern of the fringes on concave substrates, the resulting groove image depends on the position as well as the local incidence angle. Diffracted rays are not parallel, and the gratings possess focal (imaging) properties superposed to dispersive ones.

After exposure, the pattern is etched into the substrate coated with the photoresist film. Blazing of

**Figure 4** Holographic manufacture of concave diffraction gratings.

the grating is achieved by means of a chemical etch, possibly followed by an ion etch to obtain the desired shape. Groove density ranges from 65 to more than 5000 grooves per millimeter.

According to the setup described in **Figure 4**, the following relations can be used for the calculation of the grating constants:

$$N \times \lambda_F = \sin \delta + \sin \phi$$

$$C_f = \frac{\cos^2 \phi}{D_1} - \frac{\cos \phi}{R} - \left( \frac{\cos^2 \delta}{D_2} - \frac{\cos \delta}{R} \right)$$

$$C_a = \frac{1}{D_1} - \frac{\cos \phi}{R} - \left( \frac{1}{D_2} - \frac{\cos \delta}{R} \right)$$

$$C_c = \frac{\sin \phi}{D_1} \left( \frac{\cos^2 \phi}{D_1} - \frac{\cos \phi}{R} \right) - \frac{\sin \delta}{D_2} \left( \frac{\cos^2 \delta}{D_2} - \frac{\cos \delta}{R} \right)$$

## The Photodiode Principle

The photodiode is a semiconductor-based light-sensitive element, generating a current proportional to the illumination of the P–N junction (see **Figure 5**).

N-Type materials are intrinsic three-dimensional (3D) crystals of silicon or germanium subjected to

controlled impurification with chemical elements from the Va column of the periodic table (e.g., arsenic or phosphorous), behaving as a semiconductor because of the availability of unbound electrons belonging to the doping element atoms.

P-Type materials are intrinsic 3D crystals of silicon or germanium subjected to controlled impurification with chemical elements from the IIIa column of the periodic table (e.g., boron or aluminum), behaving as a semiconductor due to the availability of holes induced by the doping element atoms.

In semiconductors, the energy gap between the valence band and conduction band is relatively low. In N-type semiconductors, the Fermi level (defined as the highest energy level within a crystal populated by electrons at a temperature of absolute zero) is situated closer to the conduction band than in P-type semiconductors. Unbound electrons, at higher doping levels, are readily pushed into the conduction band with a small amount of energy transfer. In P-type semiconductors, the Fermi level is situated close to the valence band. Absorption of external energy results in an electron transfer at the Fermi level, leaving holes in the valence band. Further, energy transferred from external sources pushes electrons into a hole, generating other holes. The bound

**Figure 5** The photodiode functioning principle.

state of the electron is replicated in a new location, providing the appearance of a hole moving toward the opposite direction.

In a P–N junction generated in a single silicon or germanium crystal, the Fermi level is unique. Due to doping, the conduction and valence bands have different energies throughout the crystal, as can be seen from **Figure 5**. The neutral transition region within the P–N junction is called the depletion layer. When low-energy light strikes the photodiode, unbound electrons in the N-layer are promoted in the conduction band and the bound electrons in the P-layer are pushed onto the Fermi level. When higher-energy light strikes the photodiode, electrons from the Fermi level in the N-layer are promoted to the conduction

band, while valence electrons on the N-layer are forced over the Fermi level. Thus, the crystal becomes polarized due to electron concentration in the conduction band through the N-layer and hole concentration in the valence band through the P-layer. In the depletion layer, the electric field accelerates electrons toward the N-layer and holes toward the P-layer, resulting in a positive charge collected at the anode and a negative one placed on the cathode of the photodiode.

Controlling the thickness of the P, N, and depletion layers, as well as the dopant element concentration profile through the depletion layer, the photosensitivity ( $S$ ) and the quantum efficiency (QE) are controlled. The photosensitivity represents the

ratio between the energy of the incident beam striking the photodiode (expressed in watts) and the resulting photocurrent (expressed in amperes). QE is the photosensitivity of a photodiode measured at a specified wavelength. One can define also the spectral response of a photodiode as the photocurrent level generated for identical incident light intensity for specified wavelengths.

However, a small current is generated through a photodiode in dark conditions, when a reversed voltage is applied. This resulting current is known as a dark current.

If a charged condenser is connected in parallel to a photodiode, electrons will flow away from the N-layer into the condenser anode, while electrons from the condenser will compensate the hole excess in the P-layer. As a consequence, the condenser is discharged. The discharge of the capacitor through the photodiode will be proportional to the light intensity inducing the N-P layer junction polarization (Figure 6).

If the parallel circuit of a photodiode and a capacitor is electronically shifted between a direct current source and a current measuring device, with a given frequency, it is possible to monitor the light intensity falling on the anode. During the first stage, the direct current source charges capacitor. If anode is illuminated, the diode switches to the conduction mode and depletes the charge on the capacitor. The condenser discharge is proportional to the light intensity. When the solid-state electronic switch shifts in the measuring device loop, the residual current on the capacitor is measured.

Another working alternative is to charge, at regular intervals, the capacitor to a specific level. The amount of current needed to recharge the capacitor is thus measured, being proportional to the light intensity falling on the diode.

A diode array consists of a series of photodiode/capacitor parallel circuits positioned side by side on a silicon chip. Each such circuit is connected via its own solid-state switch controlled by a shift register, to a common output line. The shift register is controlled over a quartz oscillator (timer). The readout cycle, corresponding to the illumination time, falls in the 100 ms range. A schematic diagram of the diode array is given in Figure 7.

## Instrumentation

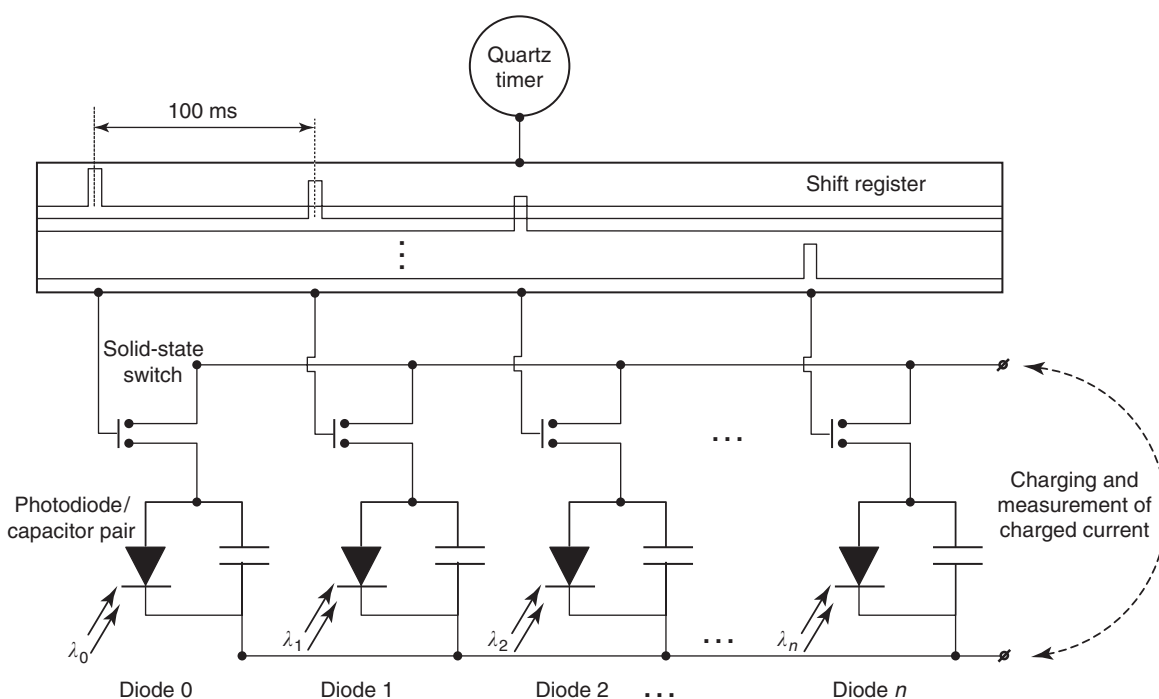

The basic design of a diode array spectrometer is given in Figure 8. Usually, spectral sources are aligned along a direction perpendicular to the sample cell. This requires a special construction of the deuterium lamp covering the UV domain (the shine through geometry) and avoids the use of a moving source selector mirror and corresponding focusing optical elements.

The shutter generally carries the holmium oxide filter (used for the calibration of the photodiode array) and the opaque surface used for the measurement of the dark current. Other optional filters can be included in order to afford fast built-in verification procedures for the spectrometer working parameters (e.g., neutral density glass filter for verification and calibration of absorbance scale in the visible domain).

Incident light is focused on the sample cell. The transmitted radiation is refocused by means of lenses and collimated through the polychromator entrance slit, thus dispersed on the fixed holographic concave diffraction grating. Dispersed wavelengths are sampled on the photodiode array elements, positioned in the flat focal plane. The spectrum is obtained by electronic scanning through the sensitive receptor.

**Figure 6** Working principle of a photodiode array element.

**Figure 7** Schematic diagram of a photodiode array.

**Figure 8** Single-beam basic configuration of a diode array spectrometer.

Filters for reducing stray light due to the multiple high-order reflections are placed directly on the active receptor of each photodiode.

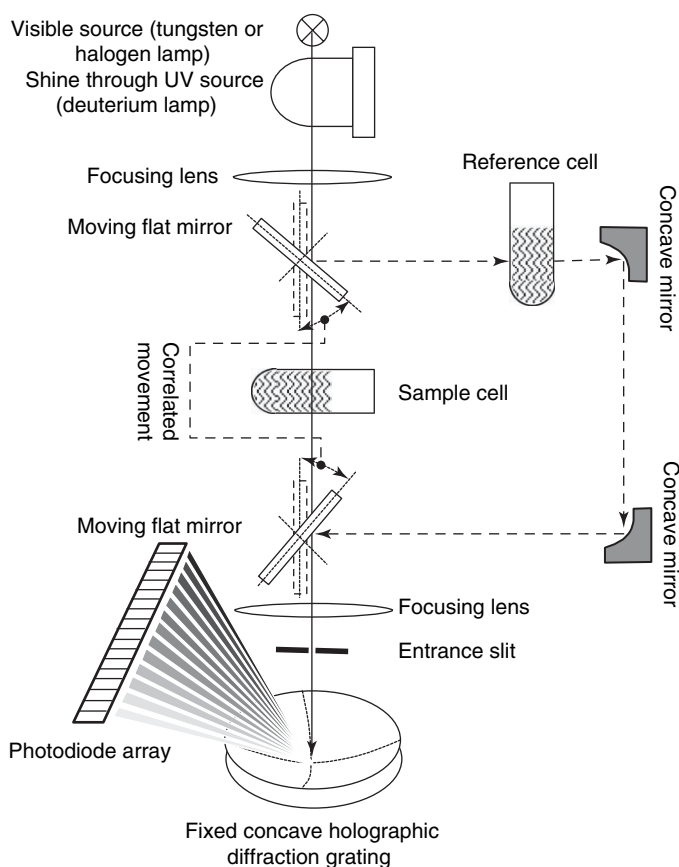

Some commercially available instruments are based on the double-beam design (see **Figure 9**). In such cases, moving beam directors (generally movement correlated flat mirrors) are used for alternatively orienting the incident beam on the reference cell and the sample cell, respectively. By controlling the movement of the flat mirrors and introducing auxiliary focusing optical reflective elements, multiple radiation beams can be obtained. Up to four sample paths have been obtained in a pseudo-double-beam design.

Some other spectrometers use different concave gratings positioned back to back. With one of the gratings, the low-resolution acquisition of the whole spectrum is achieved, while with the second grating, reduced spectral intervals are measured successively with a higher resolution.

In order to increase the resolution, dual-geometry polychromators with separate UV and visible entrance slits are also available. Each of the spectral intervals is measured sequentially on the same or on different photodiode arrays.

All these constructive alternatives suffer from increased complexity, the use of additional optically active components resulting in increased cost and

**Figure 9** Dual-beam basic configuration of a diode array spectrometer.

lower reliability together with the inherent reduction of wavelength reproducibility.

## Instrumental Parameters and Characteristics

### Resolution

The spectral resolution for diode array spectrometers is dependent upon the number of photosensitive diodes distributed in the focal plane of the concave diffraction grating. The distance, in terms of wavelength, between two adjacent diode centers is called sampling interval. Higher resolution means not only more diodes composing the array but also smaller diodes. Spectrometers for the UV–Vis domain (180–820 nm) equipped with a 1024 photodiode array will consequently ensure a resolution of  $\sim 0.6$  nm. However, a 2 nm resolution can be considered as the usual value in diode array spectrometry, which means significantly lower capabilities compared to resolutions of 0.5, 0.2, and even 0.1 nm, which is quite usual for scanning instruments. The basic requirement in spectrometry is that the

sampling interval should be at least 10 times lower than the natural bandwidth (NBW) of the sample signal. For UV–Vis spectrometric applications on solutions, the NBW characterizing signals are generally higher than 20 nm, resulting in the acceptance of a 2 nm sampling interval. However, diode array spectrometry does not cover applications requiring high-resolution spectral acquisition. The influence of the sampling interval on resolution and the resulting spectra are illustrated in **Figure 10**.

### Dynamic Range

The dynamic range, defined as the ratio between maximum and minimum absorbance measured with 1% accuracy, is limited at high absorption values by the stray light and at low absorption levels by the noise.

Stray light generated by Fresnel reflection on lens surfaces, air bubbles in glass, and diffraction at aperture edges is less important in diode array instruments compared to conventional spectrometers because of less complex construction and lower optical surfaces. The stray light in diode array

**Figure 10** Resolution in diode array spectrometry.

spectrometry can be controlled by making measurements at absorption wavelengths in the neighborhood of the maximum, considering the inherent high wavelength reproducibility of diode array instrumentation.

Noise can be controlled in diode array spectrometry by spectral averaging. The Fellgett advantage (noise reduction equals the square root of acquired data points) leads to a significant improvement of the signal-to-noise ratio. Large bandwidth acquisition not only reduces noise but also lowers sensitivity.

### Fast Spectral Acquisition

The simultaneous sampling of all spectral channels by means of diode array spectrometry leads to real-time spectral data acquisition (usually 0.1 s for the whole spectrum). Data processing and storage may add a supplementary 0.5 s delay. Consequently, diode array spectrometry is a first choice for dynamic system measurements (e.g., flow injection analysis and liquid chromatography detection, process control, fast kinetic measurements). Spectral averaging capabilities represent a corollary of the increased acquisition speed.

Statistical information derived from spectral averaging represents an additional benefit. Calculation of standard deviation for each data point can be used to detect bad results or to select the optimum wavelength for a single-component analysis. Statistic information is also of particular importance in curve-fitting multicomponent analysis.

### Wavelength Resettability

Diode array instruments have no main moving optical elements; therefore, no mechanical errors or drift arise. Consequently, the widely accepted rule in scanning spectrometry emphasizing that an accurate quantitation requires the use of the absorption maximum as analytical wavelength is no longer critical for diode array instruments. Therefore, such a choice, especially in the case of multicomponent analysis, should be focused only on reasons related to selectivity.

### Multiwavelength Acquisition and Internal Referencing

Multiwavelength acquisition is an important tool for multicomponent analysis. The calculation of absorbance ratios at different wavelengths inside an absorption band or belonging to different absorption bands leads to confirmatory analysis and band purity check.

The internal referencing minimizes random, flow-induced effects and drifts. The principle is based on the subtraction, from the experimental values measured on a given spectral interval, of a baseline absorption value determined outside the analytical range, obtained with the same radiation source. This reduces many wavelength-dependent errors resulting from the spectral source instability or sample positioning. The effect is increased when a mean value of absorption, on wavelength interval, is used instead of a single reference value. The technique turns the single-beam instrumentation into a pseudo-dual-beam one.

### Sensitivity

The sensitivity should be considered as the ability of an instrument to detect and quantify low concentrations of the target compound. In absorption spectrometry, low concentration of the analyte means high transmitted radiation levels. This is the reason why the poorer sensitivity of silicon-based photodiodes compared to photomultipliers or coupled charge detectors is in fact not so important. The relatively lower sensitivity of photodiodes is also compensated

by low electronic noise levels and increased stability to intense radiations.

Photodiode array elements have also reduced optically sensitive area compared to a single detector. However, overall light intensity within a polychromator is higher than for the case of a scanning instrument, resulting in a compensatory effect.

Increasing the measurement time also induces sensitivity improvement due to noise reduction. Spectral averaging, however, should not be overestimated, as long as drift measurement errors will limit the acquisition duration.

### Reversed Optics

In scanning instruments, the sample is placed after the exit slit of the monochromator and in front of a wide acceptance angle detector (forward optics). In order to avoid ambient stray light to reach the detector, light-tight sample areas are required.

Diode array instruments have reversed optics (see Figure 11), which means that the sample is placed in front of the narrow-acceptance-angle entrance slit of the polychromator. Consequently, ambient stray light does not essentially affect measurements, even in the case of open sample area. Based on the same assumptions, fluorescence induced in samples affects diode array instruments to a lesser extent compared to the forward optics setup.

Open sample area improves productivity and allows easier accessory installation.

Forward and reversed optics are also discussed in terms of influence on sample stability. Reversed optics increases the probability of decomposition of photolabile compounds, because the whole wavelength range is passed through the sample. These are by no means conclusive results, as it is difficult to compare effects of a single full wavelength fast exposure of the sample (produced with a reversed optics instrument) with those of a cumulative long-term exposure made by a scanning instrument. Both examples of induced sample decomposition as well as successful analysis of well-known photosensitive compounds by means of diode array instrumentation have been reported in the literature.

### Built-in Calibration and Verification Features

By means of internal software routines, the emission lines of the deuterium source ( $\alpha$  line – 656.1 nm and  $\beta$  line – 486 nm, respectively) are checked for focusing on the corresponding preset  $i, j$  photodiodes from the array. This is made by sampling photodiode positions  $(i - a; i + a)$  and  $(j - a; j + a)$ , respectively. If deviations are higher than  $\pm 1$  nm (accepted displacement depends on the resolution of the instrument), the

**Figure 11** Comparative influence of ambient stray light and sample fluorescence on scanning and diode array instrumentation, respectively.

logic identification number of each diode in the array is redefined. For this purpose, the diode array contains additional sensitive elements placed on the right- and left-hand sides of its active length.

Wavelength accuracy is usually checked with the holmium oxide filter (absorption maxima at 361, 453.7, and 536.7 nm, respectively). Such a filter is brought in the optical path of the instrument by means of the shutter.

Alternatively, the shutter may introduce an opaque filter in the instrument optical path. Sampling each diode from the array for residual current with the highly absorbing filter placed in front of the entrance slit provides the dark current test result. Dark current values higher than a maximum accepted level indicate a system malfunction.

## Applications

Diode array spectrometry covers a broad range of wavelengths, from soft X-rays to the near-infrared (NIR) domain. A typical diode array spectrometer is designated to make spectral measurements from 200 to 1200 nm, with a resolution of 1 nm. A complete spectrum can be obtained in less than 100 ms. Due to these characteristics, this technique has been considered as a useful technique in different branches of analytical sciences (quantitative and qualitative determination) as well as in fundamental research.

Diode array spectrometers have been used extensively for pharmaceutical applications, mainly when the samples are not very complex and a

multicomponent procedure can be applied. For that purpose, absorption at a large number of wavelengths can be measured simultaneously, providing spectral information for solving the unknown concentration of multicomponent samples. Spectral acquisition speed represents a valuable tool for automated dissolution test applications. The high reproducibility and reliability are also cited as real advantages, demonstrating instrument performance stability over time.

NIR spectrometers based on InGaAs diode array have been realized and successfully used for the determination of nitrogen (protein origin) and water content in citrus leaves. Measurement in the 900–1800 nm spectral interval revealed a broad spectral band, with a maximum situated at ~1425 nm. This band for fresh whole leaf differs significantly from one for dried powdered leaf due to the abundant water masking the nitrogen features in the NIR spectrum.

Some other major applications of NIR diode array spectrometry are summarized in **Table 1**.

Recently, diode array systems have been used in fast transient absorption or chemiluminescence measurements due to their capability of providing extensive real-time spectral data. Enzyme kinetics as part of biochemistry relies on fast spectral multi-wavelength acquisition. At low costs, diode array instruments are ideal for portable microfluidic bioanalyzers and emerging large-scale integrated microfluidic technologies.

The use of a commercial diode array spectrometer to study the rapid reaction kinetics has great

**Table 1** Major application fields for NIR diode array spectrometry

<i>Chemical composition</i>	<i>Bulk properties</i>	<i>Physical properties</i>
Protein	Density	Particle size/fiber diameter
Humidity/water content	Digestibility	Temperature
Hydrocarbons	Viscosity	Mechanical properties
Carboxylic acids	Motor fuel octane number	Thermal and mechanical pretreatment
Amines	Reid vapor pressure of gasoline	Molar masses of polymers
Oil/fat	Seed germination	
Sucrose/glucose		
Additives in fuels	Distillation parameters	
	Fruit ripeness	
	Total dissolved solids	

potential due to the simultaneous acquisition of wavelength data. Addition of an optimized stopped-flow accessory makes such an approach affordable. For example, the reaction of Ellman's reagent with thioglycerol was used to illustrate how this combination can be used to acquire complex data, which are subsequently processed using multivariate global analysis methods. UV-Vis absorption cross-sections and atmospheric photolysis rates of some pollutants ( $\text{CH}_2\text{Br}_2$ ,  $\text{CH}_2\text{I}_2$ ,  $\text{CH}_2\text{BrI}$ ,  $\text{CH}_2\text{ICl}$ ;  $\text{CF}_3\text{I}$ ,  $\text{CH}_3\text{I}$  and  $\text{C}_2\text{H}_5\text{I}$ ) were studied by means of diode array instruments with spectral resolution of 0.6 nm. It has been proved that the reaction of these target compounds with HO radical is the dominant atmospheric loss process.

Diode array spectrometers are often used as multichannel analyzers designated for real-time spectral analysis. Spectral analysis provides useful information on the color characteristics of numerous materials and light sources. Spectral analysis techniques that use diode array technology are widely used in analyzing lamps and LED's emission and in quantifying the reflectance, transmittance, color, and haze of many materials. These instruments offer high sensitivity, low noise, and broad spectral response. Optionally, integral fiber cables, connecting the spectrometer to the light source, are used. Cables offer additional flexibility for remote positioning of the spectrometer. Spectrometers can be packed in self-contained compact enclosures that are easily connected to a computer via a serial port.

Another class of applications refers to environmental pollution monitoring. For instance, some atmospheric pollutants (ammonia, nitrogen oxides, and, in some cases, sulfur dioxide) in the flue gas stream can be analyzed simultaneously by means of UV spectrometry. Their determination at the nanogram per liter level can be achieved with a process

analyzer based on UV absorbance monitoring using diode array technology. Hydrocarbon monitoring in polluted water can be achieved by NIR diode array instruments after liquid-liquid extraction in chlorinated solvents.

Online applications are by far the most important utilization of diode array spectrometry. High-performance liquid chromatography, supercritical fluid chromatography, capillary electrophoresis, and flow-injection techniques produce enhanced sensitivity and structure-related information due to coupling with diode-array-based detectors. Emission of the microwave-induced plasma generated in atomic emission detectors for capillary gas chromatography is also analyzed by means of UV-Vis diode array instruments.

## Derivative Techniques

F Vogt, Arizona State University, Tempe, AZ, USA

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Derivative spectroscopy makes use of the first- and higher-order derivatives of absorbance or transmission spectra with respect to wavelength for improving qualitative and quantitative analysis. The two main advantages of derivative spectroscopy are (1) to enhance spectral features facilitating the analyses of samples containing substances with very similar absorption spectra and (2) to suppress large, broad background signals overlaying the absorption features of interest.

The concept of differentiating spectral data was first introduced in the 1950s, but it received little attention primarily because of experimental difficulties in generating derivative spectra with early ultraviolet (UV)/visible (Vis) spectrophotometers. Use of mathematical or optical methods to generate derivative spectra became feasible with the advent of microprocessors and microcomputers in the late 1970s. Nowadays, most instruments offer at least the first and second numerical derivatives as a standard feature. The combination of derivative spectroscopy and chemometrics for calibration and data evaluation has further increased the popularity of this technique. Derivative techniques are applied especially in UV spectroscopy for pharmaceutical, biomedical, and environmental measurement tasks and in food research.

In this article, the mathematical and experimental methods for generation and evaluation of derivative spectra are discussed.

### Generating Derivative Spectra

#### General

The absorbance spectrum  $A(\lambda)$  is linearly related to the absorption pathlength  $L$ , the wavelength-dependent molar absorption coefficient  $\varepsilon(\lambda)$ , and the concentration of an analyte  $c$ :

$$A(\lambda) = L \cdot \varepsilon(\lambda) \cdot c \quad [1]$$

There is a linear relationship between the  $n$ th-order derivative spectra and the concentration of a chemical compound in the analyzed samples:

$$\frac{d^n A(\lambda)}{d\lambda^n} = L \cdot \frac{d^n \varepsilon(\lambda)}{d\lambda^n} \cdot c \quad [2]$$

Usually, derivative orders  $n \leq 4$  are exploited in practical applications but second-order derivative spectroscopy is the most popular one.

The effect of differentiation is explained by means of Figure 1 independent from the technique used for determining derivative spectra: two synthetic Gaussian absorption bands of different width are shown in the top left graph. The first derivative (top right graph) describes how much the absorbance changes with wavelength. It is zero at wavelengths below and above the absorbance bands and it passes through zero for the maximum absorption. It is positive for wavelength below the maxima since the absorption increases. For wavelengths larger than the maxima's wavelengths the absorption decreases and hence the first derivative is negative. The most characteristic features of the second derivative (bottom left) are the negative band with minimum at  $\lambda_{\max}$  and the two positive satellite bands on either side of the main band. Note that the number of determined bands equals the order of the derivative plus one; for instance, four for the third derivative (bottom right graph). By comparing both absorption bands the tendency of derivatives to suppress broader features and pronounce narrower ones is evident.

Another example involving experimental data acquired from a sample of 100 ppm gaseous nitric oxide (NO) diluted in nitrogen ( $N_2$ ) is given in Figure 2.  $I_0(\lambda)$  denotes the background spectrum obtained from a sample of pure  $N_2$  and  $I_{NO}(\lambda)$  the transmission spectrum of the NO sample. The low and featureless difference between  $I_0(\lambda)$  and  $I_{NO}(\lambda)$  makes NO quantification and the discrimination of other absorbers (not shown) difficult. The first derivative  $dI_{NO}(\lambda)/d\lambda$  and even more the second  $d^2 I_{NO}(\lambda)/d\lambda^2$  largely enhance the NO absorption features. Especially the second derivative suppresses the large background spectrum, which does not contain information but limits the resolution of the analog-to-digital conversion.

Derivative spectra can be obtained by mathematical, electronic, or optical methods. Mathematical approaches are the most common ones since they can be performed without additional hardware – a software package extension is sufficient. Electronic differentiation has been proposed but is not applied widely. Optical differentiation demands more elaborated setups; however, better results are obtained in comparison to the other two alternatives. This is discussed below.

**Figure 1** Synthetic example demonstrating numerical derivative spectra up to third order derived from a synthetic absorbance spectrum – the lower left graph compares the Savitzky–Golay method to the noise sensitive difference approach [3].

**Figure 2** Optical differentiation enhances low gaseous nitric oxide (NO) absorption features overlaid by a broad background spectrum.

### Numerical Differentiation Techniques

**Difference method** The most straightforward method for achieving first derivatives  $D_1$  of discretely sampled absorbance signals  $A$  is to calculate the difference of two consecutive measurement points number  $i$  and  $i + 1$  divided by the distance of the two points:

$$D_1(i) = \frac{A_{i+1} - A_i}{i + 1 - i} = A_{i+1} - A_i$$

The second derivative  $D_2$  is determined from the first derivative  $D_1$  in the same way:

$$D_2(i) = \frac{D_1(i+1) - D_1(i)}{i + 1 - i} = (A_{i+2} - A_{i+1}) - (A_{i+1} - A_i) = A_{i+2} - 2 \cdot A_{i+1} + A_i \quad [3]$$

Although this approach is easy to understand one should not use it for calculating derivatives since noise is amplified largely. The noise susceptibility is demonstrated in the lower left graph of **Figure 1** by comparing second-order derivatives obtained with this difference method [3] to the Savitzky–Golay approach discussed in the following paragraph, which is much less susceptible to noise.

**Savitzky–Golay method** This method determines a derivative spectrum by moving a spectral window comprising  $2 \cdot n + 1$  measurement points over an absorbance spectrum. Then a polynomial of order  $m$

$$P(\lambda) = a_0 + a_1 \cdot \lambda + a_2 \cdot \lambda^2 + \dots + a_m \cdot \lambda^m \quad [4]$$

is fitted to the measurement points inside the spectral window. This fit polynomial introduces smoothing,

which is dependent on the user selectable parameters  $n$  and  $m$ . From the resulting fit parameters  $a_0 \dots a_m$ , the derivatives at the window center  $\lambda_0$  can be derived easily:

$$\begin{aligned} \left. \frac{dP(\lambda)}{d\lambda} \right|_{\lambda_0=0} &= a_1 + a_2 \cdot 2 \cdot \lambda_0 \\ &\quad + \dots + a_m \cdot m \cdot \lambda_0^{m-1} = a_1 \\ \left. \frac{d^2P(\lambda)}{d\lambda^2} \right|_{\lambda_0=0} &= a_2 \cdot 2 + \dots + a_m \cdot m \cdot (m-1) \cdot \lambda_0^{m-2} \\ &= 2 \cdot a_2 \\ \left. \frac{d^3P(\lambda)}{d\lambda^3} \right|_{\lambda_0=0} &= a_3 \cdot 3 \cdot 2 + \dots + a_m \cdot m \\ &\quad \cdot (m-1) \cdot (m-2) \cdot \lambda_0^{m-3} = 6 \cdot a_3 \\ &\vdots \end{aligned} \quad [5]$$

Due to the design of this differentiation technique  $\lambda_0$  is located at the center of the window. Hence,  $\lambda_0 = 0$  can be assumed from a least-squares point of view – this has no physical meaning, though.

Once the derivatives are determined at  $\lambda_0$ , the window is moved one measurement point to the right followed by a polynomial fit inside this new window. Derivatives at the centers of these new windows are calculated again by means of [5]. This procedure is continued until the window reaches the end of the spectrum. A consequence of this mathematical method is that  $n$  data points are lost for the derivative spectra at both ends of the spectrum. The window width is a central parameter of the Savitzky–Golay differentiation method. A narrow window preserves more spectral features whereas a wider one introduces more smoothing. For example, **Figure 1** has been generated using a fourth-order polynomial and a window width of 21 points.tpb 1pc

### Electronic Differentiation Techniques

The output signal of a detector is proportional to the wavelength-dependent radiation intensity  $I(\lambda)$  illuminating the detector element. If a monochromator scans continuously over a certain wavelength interval, the measured radiation intensity is transformed into a time-dependent signal  $I(t)$ . An appropriate preamplifier modifies  $I(t)$  to an output voltage through an amplification factor  $g$ :

$$U_{\text{preamp}}(t) = g \cdot I(t) \quad [6]$$

$U_{\text{preamp}}(t)$  is then fed into an electronic differentiator. The basic electronic circuit for differentiating time-dependent signals utilizes an operational amplifier, a resistor  $R$ , and a capacitor  $C$ . This electronic

differentiator outputs:

$$U_{\text{out}}(t) = -R \cdot C \cdot \frac{dU_{\text{preamp}}(t)}{dt} \quad [7]$$

The capacitor is the main component of this circuit as it blocks DC parts of  $U_{\text{preamp}}(t)$  at the input of an operational amplifier and lets only AC parts pass, i.e., changes in  $U_{\text{preamp}}(t)$ . If the input voltage changes slowly, the output voltage is low; if there are fast changes on the input, the output voltage is high. Combining [6] and [7] leads to a signal, which is proportional to the time-dependent change of the intensity  $I(t)$  measured by the detector, i.e., the first derivative:

$$U_{\text{out}}(t) = -R \cdot C \cdot g \cdot \frac{dI(t)}{dt}$$

Given a known wavelength scan rate,  $dI(t)/dt$  can be transformed to  $dI(\lambda)/d\lambda$ . Cascaded circuits can be designed in order to determine higher derivatives.

### Optical Differentiation Techniques

Optical techniques for generating derivatives are based on wavelength-modulation strategies. A prominent method utilizes a laser diode, whose emission wavelength is tuned continuously over a certain wavelength range by adjusting the laser current. Another common wavelength-modulation technique is shown in **Figure 3**: a monochromator, usually a reflection grating, scans stepwise over the selected wavelength range. At every discrete wavelength position  $\lambda_0$ , the monochromator vibrates around an axis of rotation sinusoidally back and forth several times. In this way, the wavelength selected by the monochromator/slit configuration is a function of time. In the following equation,  $a$  denotes the amplitude of the modulation and  $\omega$  the vibration or modulation frequency:

$$\lambda(t) = \lambda_0 \pm \Delta\lambda(t) = \lambda_0 + a \sin(\omega t) \Leftrightarrow \lambda - \lambda_0 = a \sin(\omega t) \quad [8]$$

The transmission spectrum (Beer's law)

$$I(\lambda) = I_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c] \quad [9]$$

with  $I_0(\lambda)$  as emission spectrum of the light source is expanded into Taylor's series around  $\lambda_0$ :

$$\begin{aligned} I(\lambda) &= I(\lambda_0, t) \\ &= \sum_{n=0}^{\infty} \frac{1}{n!} \cdot I^{(n)}(\lambda_0) \cdot (\lambda - \lambda_0)^n \end{aligned}$$

**Figure 3** Principle of wavelength modulation for generation of optical derivatives.

In [10],  $I^{(n)}(\lambda_0)$  denotes the  $n$ th derivative of the transmission  $I(\lambda)$  with respect to wavelength  $\lambda$  at the position  $\lambda_0$ . This expansion [10] is abbreviated to the order of required derivative; for instance, to second order. Using [8] in [10] derives an approximation of the transmission spectrum with  $I'(\lambda_0)$  and  $I''(\lambda_0)$  denoting the first and second derivatives at  $\lambda_0$ , respectively:

$$\begin{aligned} I(\lambda) &\approx I(\lambda_0) + I'(\lambda_0) \cdot a \sin(\omega t) \\ &\quad + \frac{1}{2} \cdot I''(\lambda_0) \cdot [a \sin(\omega t)]^2 \\ &= I(\lambda_0) + I''(\lambda_0) \cdot \frac{a^2}{4} + I'(\lambda_0) \cdot a \sin(\omega t) \\ &\quad - I''(\lambda_0) \cdot \frac{a^2}{4} \cos(2\omega t) \end{aligned} \quad [11]$$

In [11], the following formula was used:

$$\sin^2(\omega t) = \frac{1}{2} \cdot [1 - \cos(2\omega t)]$$

The wavelength modulation of the transmission intensity  $I(\lambda)$  induces in [6] a DC detector signal as well as AC signals with frequency  $\omega$  and higher harmonics. Due to the factorial factor  $1/n!$  [10], higher harmonic signals are decreasing quickly with  $n$ . In second-order derivative spectroscopy, the preamplifier output is directed to three different narrow band filters: a low pass filter determines the DC component and two lock-in amplifiers with reference frequencies  $\omega$  and  $2\omega$  measure the AC components of the signal at these frequencies. The resulting three signals are proportional to the transmission spectrum, the first and second derivatives:

$$\text{DC}(\lambda_0) \propto I(\lambda_0) + I''(\lambda_0) \cdot \frac{a^2}{4} \approx I(\lambda_0)$$

$$\text{AC}_\omega(\lambda_0) \propto I'(\lambda_0) \cdot a \quad [12]$$

$$\text{AC}_{2\omega}(\lambda_0) \propto -I''(\lambda_0) \cdot \frac{a^2}{4}$$

The approximation made in the first line of [12] is allowed since the contribution from the second derivative to the DC term is usually a few orders of magnitude lower than  $I(\lambda_0)$ . If the modulation amplitude  $a$  is constant during all measurements,  $a$  and the factor  $-1/4$  are just scaling factors. Once these three signals are measured at  $\lambda_0$  the monochromator is moved to the next wavelength position, and so forth.

## Evaluation of Derivative Spectra

### Suppression of Background Spectra or Matrix Effects

Baseline drifts due to lamp and detector instabilities or due to optics getting dirty cause major concentration errors in spectrophotometry. Because background drifts are usually broad compared to absorption features suppression of such baseline shifts can be achieved by differentiating the spectra. **Figures 1 and 4** are based on the same spectroscopic features. However, in **Figure 4** (top left graph) a background drift unequal to a polynomial was simulated additionally. The first-derivative spectra (**Figures 1 and 4** right graphs) are slightly different, second and higher orders are basically equal. Hence, by means of second or higher derivatives such disturbing background drifts can be removed.

### Enhancing Low and Similar Absorbance Features

In spectrophotometry, the relevant absorption features are usually overlaid by a broad background

**Figure 4** Suppression of broad spectral features assigned to baseline shifts or matrix effects.

spectrum. Even if this background spectrum is stable in time, it limits the resolution of the analog-to-digital conversion. If most bits are needed for the background spectrum, which does not contain information, only a low number of bits are left for resolving the relevant absorption features. This limits the concentration resolution.

Experimental examples of enhancing minute spectral differences are given in **Figures 2** and **5**: in **Figure 2**, data obtained from a gaseous sample are shown; in **Figure 5**, aqueous samples of benzene, toluene, and *p*-xylene are considered. All three UV transmission spectra (left column of **Figure 5**) look very similar and are mainly determined by the emission spectrum of the light source; therefore, no compound-specific spectral features can be detected. Small differences are found in the first optical derivative spectra and even more in the second optical derivatives. These derivatives enable the discrimination of the analytes and the multicomponent quantification can be improved largely.

### Determination of Analytes

Derivatives of absorbance spectra

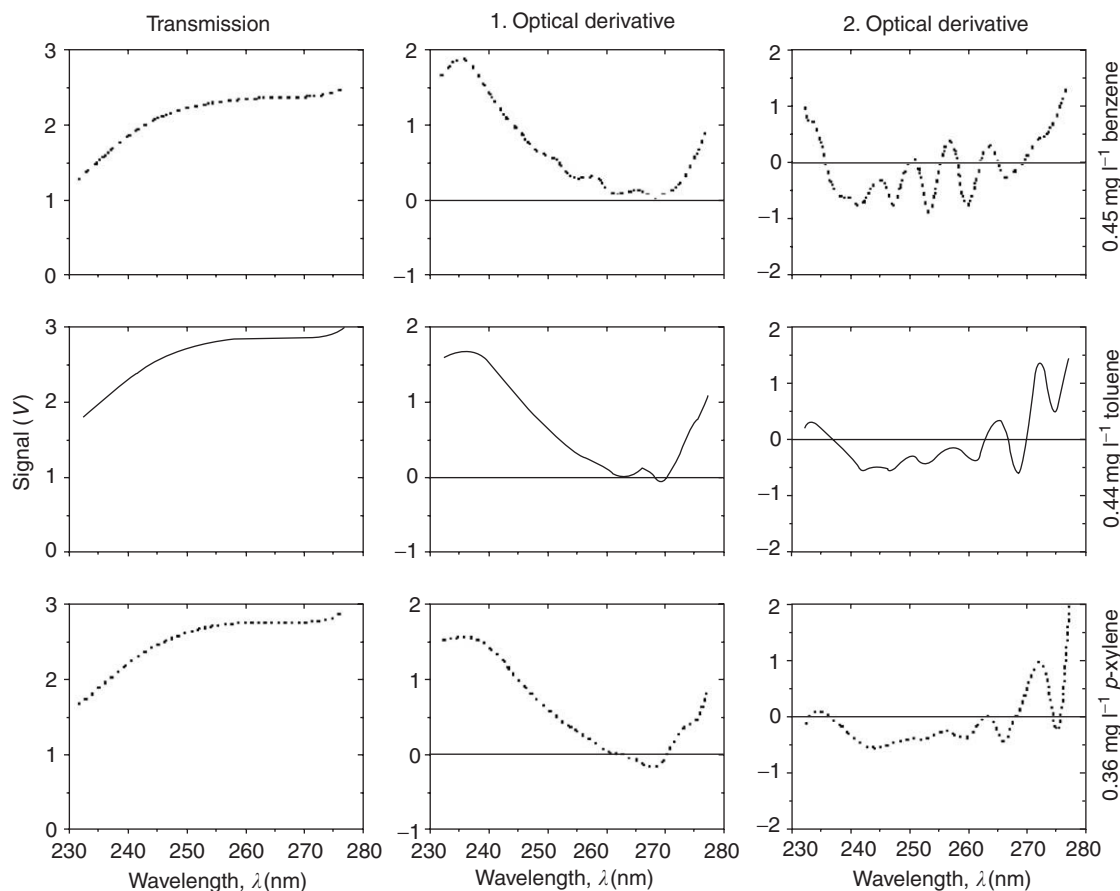

$$A(\lambda) = \ln \left[ \frac{I_0(\lambda)}{I(\lambda)} \right] = L \cdot \varepsilon(\lambda) \cdot c \quad [13]$$

are directly proportional to concentration of analytes [1]. In the following, it will be shown, how the first and second derivatives of the absorption spectra  $A'(\lambda)$  and  $A''(\lambda)$  are derived from the measured background and transmission spectrum as well as their first and second derivatives. All three types of derivatives, i.e., numerical, electronic, and optical, can be used in the same way for this purpose. Differentiating the transmission spectrum [9] using the product rule results in:

$$I'(\lambda) = I'_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c] - L \cdot \varepsilon'(\lambda) \cdot c \cdot I_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c] \quad [14]$$

In order to get a linear relation between measured data  $I'(\lambda)$ ,  $I'_0(\lambda)$ ,  $I_0(\lambda)$ , and concentration  $c$ , this equation is divided by [9]:

$$\begin{aligned} \frac{I'(\lambda)}{I(\lambda)} &= \frac{I'_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c]}{I_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c]} \\ &\quad - L \cdot \varepsilon'(\lambda) \cdot c \cdot \frac{I_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c]}{I_0(\lambda) \exp[-L \cdot \varepsilon(\lambda) \cdot c]} \\ &= \frac{I'_0(\lambda)}{I_0(\lambda)} - L \cdot \varepsilon'(\lambda) \cdot c \\ &\Downarrow \\ A'(\lambda) &= L \cdot \varepsilon'(\lambda) \cdot c = \frac{I'_0(\lambda)}{I_0(\lambda)} - \frac{I'(\lambda)}{I(\lambda)} \end{aligned} \quad [15]$$

**Figure 5** Enhancing the minute differences of analytes with very similar absorption spectra using optical derivative spectra. (Reprinted with permission from Vogt F, Tacke M, Jakusch M, and Mizaikoff B (2000) An ultraviolet spectroscopic method for monitoring aromatic hydrocarbons dissolved in water. *Analytica Chimica Acta* 422: 187–198; © Elsevier; cf. Erratum: (2001) *Analytica Chimica Acta* 431: 167.)

Differentiating [14] a second time and dividing the resulting equation by [9] relates the concentration to a measured transmission spectrum and its first and second derivatives:

$$\begin{aligned} \frac{I''(\lambda)}{I(\lambda)} &= \frac{I_0''(\lambda)}{I_0(\lambda)} - L \cdot \varepsilon''(\lambda) \cdot c \\ &\quad - 2 \cdot \frac{I_0'(\lambda)}{I_0(\lambda)} \cdot \underbrace{\varepsilon'(\lambda) \cdot L \cdot c}_{(*)} \\ &\quad + \left( \underbrace{(L \cdot \varepsilon'(\lambda) \cdot c)^2}_{(*)} \right)^2 \end{aligned}$$

The (\*)-marked terms in the latter equation are replaced by the right-hand side of [15]:

$$\begin{aligned} \frac{I''(\lambda)}{I(\lambda)} &= \frac{I_0''(\lambda)}{I_0(\lambda)} - L \cdot \varepsilon''(\lambda) \cdot c \\ &\quad - 2 \cdot \frac{I_0'(\lambda)}{I_0(\lambda)} \cdot \left( \frac{I_0'(\lambda)}{I_0(\lambda)} - \frac{I'(\lambda)}{I(\lambda)} \right) \\ &\quad + \left( \frac{I_0'(\lambda)}{I_0(\lambda)} - \frac{I'(\lambda)}{I(\lambda)} \right)^2 \end{aligned}$$

$$\begin{aligned} &= \frac{I_0''(\lambda)}{I_0(\lambda)} - L \cdot \varepsilon''(\lambda) \cdot c - 2 \cdot \left( \frac{I_0'(\lambda)}{I_0(\lambda)} \right)^2 \\ &\quad + 2 \cdot \frac{I_0'(\lambda)}{I_0(\lambda)} \cdot \frac{I'(\lambda)}{I(\lambda)} + \left( \frac{I_0'(\lambda)}{I_0(\lambda)} \right)^2 \\ &\quad - 2 \cdot \frac{I_0'(\lambda)}{I_0(\lambda)} \cdot \frac{I'(\lambda)}{I(\lambda)} + \left( \frac{I'(\lambda)}{I(\lambda)} \right)^2 \end{aligned}$$

Rearranging this equation results in the final equation relating the measured data linearly to the concentration  $c$ :

$$\begin{aligned} A''(\lambda) &= L \cdot \varepsilon''(\lambda) \cdot c = \left\{ \frac{I_0''(\lambda)}{I_0(\lambda)} - \left( \frac{I_0'(\lambda)}{I_0(\lambda)} \right)^2 \right\} \\ &\quad - \left\{ \frac{I''(\lambda)}{I(\lambda)} - \left( \frac{I'(\lambda)}{I(\lambda)} \right)^2 \right\} \\ &\approx \frac{I_0''(\lambda)}{I_0(\lambda)} - \frac{I''(\lambda)}{I(\lambda)} \end{aligned} \quad [16]$$

The approximation made in the third line of [16] is acceptable for several applications and simplifies experimental setups for measuring optical derivatives

because only one lock-in amplifier is needed for determining  $AC_{2\omega}$  [12].

This discussion can be easily extended to multi-component evaluation since Beer's law states that the absorbances  $A_{q=1\dots Q}$  of  $Q$  analytes superimpose linearly, i.e., [13] is replaced by:

$$\begin{aligned} A(\lambda) &= \ln \left[ \frac{I_0(\lambda)}{I(\lambda)} \right] = \sum_{q=1}^Q A_q(\lambda) \\ &= \sum_{q=1}^Q L \cdot \varepsilon_q(\lambda) \cdot c_q \end{aligned} \quad [17]$$

Equation [15] is replaced by:

$$A'(\lambda) = \frac{I'_0(\lambda)}{I_0(\lambda)} - \frac{I'(\lambda)}{I(\lambda)} = \sum_{q=1}^Q L \cdot \varepsilon'_q(\lambda) \cdot c_q \quad [18]$$

and equation [16] is replaced by:

$$\begin{aligned} A''(\lambda) &= \left\{ \frac{I''_0(\lambda)}{I_0(\lambda)} - \left( \frac{I'_0(\lambda)}{I_0(\lambda)} \right)^2 \right\} \\ &\quad - \left\{ \frac{I''(\lambda)}{I(\lambda)} - \left( \frac{I'(\lambda)}{I(\lambda)} \right)^2 \right\} = \sum_{q=1}^Q L \cdot \varepsilon''_q(\lambda) \cdot c_q \end{aligned} \quad [19]$$

Because the equations for the conventional transmission spectroscopy [17], the first [18], and the second derivative [19] are all of the same type, the following concepts can readily be adapted to all three cases. For example, in second-order derivative spectroscopy, the right-hand side of [19] is rewritten in vector notation as this facilitates the discussion, which paves the way to combine derivative spectrophotometry and chemometrics for sophisticated calibration and data evaluation tools:

$$A''(\lambda) = (L \cdot \varepsilon''_1(\lambda) \cdots L \cdot \varepsilon''_Q(\lambda)) \cdot \begin{pmatrix} c_1 \\ \vdots \\ c_Q \end{pmatrix} \quad [20]$$

If concentrations of  $Q > 1$  different analytes are to be determined,  $A''(\lambda)$  must be measured at  $N \geq Q$  different wavelength positions in order to set up an equation system:

$$\begin{pmatrix} A''(\lambda_1) \\ \vdots \\ A''(\lambda_N) \end{pmatrix} = \begin{pmatrix} L \cdot \varepsilon''_1(\lambda_1) & \cdots & L \cdot \varepsilon''_Q(\lambda_1) \\ \vdots & & \vdots \\ \vdots & \ddots & \vdots \\ L \cdot \varepsilon''_1(\lambda_N) & \cdots & L \cdot \varepsilon''_Q(\lambda_N) \end{pmatrix} \cdot \begin{pmatrix} c_1 \\ \vdots \\ c_Q \end{pmatrix} \quad [21]$$

$$\mathbf{A}''_{(N \times 1)} = \mathbf{E}_{(N \times Q)} \cdot \mathbf{c}_{(Q \times 1)}$$

Calibration samples are used to determine the calibration matrix  $\mathbf{E}$ ; the concentrations  $\mathbf{c}$  of unknown

samples can then be determined from the measurement data vector  $\mathbf{A}''$  by means of solving the (over-determined) equation system [21]. Chemometrics provide the mathematical tools for these computations.

It is important to note that, by means of this approach ([21]), overlapping spectral features can be evaluated – there is no need for isolated absorption bands.

## Instrumental Assessments

### General

The use of numerical and electronic derivatives is not free from problems concerning the signal-to-noise ratio and versatility because not only baseline drifts are suppressed by differentiating spectra, but also broad, relevant absorption features (see **Figure 4**, absorption band  $\sim 700$  wavelength units).

### Signal-to-Noise Ratio

By comparing the different y-axis scales in **Figure 1**, it is obvious that numerical derivatives generally decrease the signal level because low-frequency signal components are suppressed. On the other hand, high-frequency signal components including noise are enhanced. The combination of suppressing low-frequency signals, which mostly represent relevant spectral information, and the enhancement of high-frequency noise decreases the signal-to-noise ratio.

Because numerical derivatives are computed from spectra, which are measured with a broadband amplifier, noise at all frequencies affects the measurement spectra. Optical derivatives, however, utilize a DC amplifier with a high time constant and lock-in amplifiers with narrow bandwidth  $\delta\omega$ . Only noise with frequencies  $\omega \pm \delta\omega/2$  and  $2\omega \pm \delta\omega/2$  influences the first and second derivatives. The DC measurement can only be affected by long time drifts – AC noise is averaged out. This improves the signal-to-noise ratio compared to the numerical approach.

### Influence of the Window Width and the Modulation Amplitude on Derivatives

Of the two parameters the user has to select for the Savitzky–Golay method, the polynomial order  $m$  [4] is the less important one. Much more important is the window width  $2n+1$ . In **Figure 6**, second-derivative spectra of a synthetic absorption spectrum (**Figure 1**, upper left graph) are compared, which have been calculated using different window widths. A too narrow window does not incorporate sufficient smoothing (upper left graph) and suppresses relevant broad features – a too broad window causes artifacts

**Figure 6** Influence of the Savitzky-Golay window width on the shape of the derivatives – shown are second derivatives of the absorption spectrum plotted in the upper left graph of **Figure 1**.

**Figure 7** Influence of the modulation amplitude  $a$  [8] on the shape of a second-order derivative spectrum [19]. The example was determined by means of an aqueous sample containing approx.  $1 \text{ mg l}^{-1}$  of each benzene, toluene,  $p$ -xylene. (Reprinted with permission from Vogt F, Tacke M, Jakusch M, and Mizaikoff B (2000) An ultraviolet spectroscopic method for monitoring aromatic hydrocarbons dissolved in water. *Analytica Chimica Acta* 422: 187–198; © Elsevier; cf. Erratum: (2001) *Analytica Chimica Acta* 431: 167.)

(marked by arrows in the lower right graph). Fine tuning is necessary for a specific application in order to optimize smoothing and signal intensity (upper right and lower left graph).

Although electronic derivative spectroscopy has been proposed, such techniques never found broad acceptance or applications. One reason might be that optimizations for different applications are not

possible as the differentiation is defined unchangeable by the resistor and the capacitor of the differentiating circuit [7].

Analogous to the adjustment of the window width, different modulation amplitudes  $a$  [8] can be chosen in optical derivative spectroscopy. According to [12], larger derivative signals and hence better signal-to-noise ratio can be gained by increasing  $a$ . This was confirmed experimentally; however, a signal increase comes along with a washing out of derivative shapes and minute derivative features are lost (Figure 7). The values for the modulation amplitude given in Figure 7 are typical examples. Thus, the modulation amplitude can be optimized for different applications: if several analytes in mixtures have very similar and overlapping absorption spectra, a small modulation amplitude helps to pronounce minor differences for discrimination. If, however, clearly different absorption spectra are present, a large modulation amplitude is selected for improved signal-to-noise ratio.

## Introduction

Turbidity is an expression of the optical property of a medium, which causes light to be scattered and absorbed rather than transmitted in straight lines through the sample. The International Organization for Standardization (ISO) defines turbidity as the 'reduction of transparency of a liquid caused by the presence of undissolved matter'. It is, therefore, the opposite of clarity. The medium concerned is normally a fluid (but may be solid) in which light is

scattered by matter – usually small particles – suspended in the light path. Measurements of turbidity can be used in many analytical fields to determine the mass concentration of suspended particles in a sample and, for some simple contexts, particle size distributions. The field is hampered, however, by a lack of standardization in units, measurement devices and calibration techniques. Analytical determinations of concentrations tend to be empirical. Such methodological problems have recently driven a profusion of technical papers.

This article reviews turbidity theory, measurement principles, instrumentation systems, and applications, with particular reference to suspended sediment concentrations (SSCs) in natural waters (e.g., rivers, estuaries, and nearshore zones).

## Turbidimetry and Nephelometry

D M Lawler, University of Birmingham, Birmingham, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Turbidity is an expression of the optical property of a medium, which causes light to be scattered and absorbed rather than transmitted in straight lines through the sample. The International Organization for Standardization (ISO) defines turbidity as the 'reduction of transparency of a liquid caused by the presence of undissolved matter'. It is, therefore, the opposite of clarity. The medium concerned is normally a fluid (but may be solid) in which light is

scattered by matter – usually small particles – suspended in the light path. Measurements of turbidity can be used in many analytical fields to determine the mass concentration of suspended particles in a sample and, for some simple contexts, particle size distributions. The field is hampered, however, by a lack of standardization in units, measurement devices and calibration techniques. Analytical determinations of concentrations tend to be empirical. Such methodological problems have recently driven a profusion of technical papers.

This article reviews turbidity theory, measurement principles, instrumentation systems, and applications, with particular reference to suspended sediment concentrations (SSCs) in natural waters (e.g., rivers, estuaries, and nearshore zones).

## Definitions and Applications

### Measurement Definitions

Turbidity can be measured using the techniques of turbidimetry or nephelometry (from *nephelo* = cloud (Greek)). Turbidimetry is the measurement of turbidity by quantifying the degree of 'attenuation' of a beam of light of known initial intensity. It is usually applied to media of fairly high turbidity in which the scattering particles are relatively large (e.g., natural waters), for reasons, which will be addressed below.

Nephelometry is the measurement of turbidity by the direct evaluation of the degree of light 'scattering' taking place in the medium. It is much more appropriate to media of lower turbidity in which the suspended particles are small. Turbidimetry and nephelometry can offer considerable time-saving advantages over gravimetric methods for the determination of particle concentrations, and are non-destructive techniques.

### Typical Applications

Turbidimetry and nephelometry have found many applications in scientific laboratories and in the chemical, pharmaceutical, foodstuffs, and beverage industries. In addition, turbidimetry and nephelometry are well-established procedures wherever filtration processes have to be effected, monitored, and controlled. Within the hydrological sciences, and water supply and wastewater management industries, turbidity values can act as simple and convenient surrogate measures of the concentration of suspended solids, sulfate ions (which are precipitated as  $\text{BaSO}_4$  in acidic media (HCl) with barium chloride), and other particulate material, and remain one of the most common applications of turbidimetry. Also, atmospheric and space physicists effect nephelometric analyses because of the importance of dust particles to radiation and other processes. In quantitative chemical and biological analysis, applications are common, especially the calculation of absolute molecular weights and dimensions of polymers in solution, as well as particle size determinations of suspended matter. Chemical profiles can also be obtained by observing turbidity changes deliberately induced by the addition of specific substances to the solution. Within microbiology, cell and bacteria growth can be monitored through the media turbidity changes such activity causes. In foodstuff manufacturing, turbidimetry is often used to monitor product quality and treatment process efficiency, especially in the dairy and brewing industries. Clarity (and hence turbidity) is also a key concern in the petrochemical industries. Determining turbidity

components – turbidity apportionment – has advanced with recent technological developments.

## Principles and Theory

Light passing through a liquid medium may be scattered and absorbed by inhomogeneities in the light path, especially suspended particles of silt, clay, algae and other plankton, microbes, organic matter, and other fine insoluble particulate substances. Bubbles and density discontinuities can also scatter light. Scattering occurs when 'a minute particle interacts with incident light by absorbing the light energy and then, as if a point light source itself, reradiating the light energy in all directions'. Absorption takes place when light is converted to other energy forms (e.g., heat) within the particle. Scattered light includes that reflected from the surface of the particle and that refracted within the particle, possibly after many internal reflections. Scattering is often accompanied by absorption.

The direct relationship, however, between turbidity data and suspended solids concentrations is weakened by the complex interactions of light energy with suspended particles. This interplay is heavily dependent on many factors, including:

- concentration of scattering particles suspended in the medium;
- size distribution of the scattering particles;
- shape, orientation, and surface condition of the scattering particles;
- refractive index of the scattering particles;
- refractive index of the suspension medium;
- wavelength of the light source employed.

Consequently, separate bodies of theory have been developed to describe the many different processes that result. At its simplest level, light intensity is reduced during transmission through a collection of scattering particles in a sample according to an attenuation function of the form:

$$I = I_0 e^{-\tau l} \quad [1]$$

where  $I_0$  is the initial beam intensity,  $I$  the beam intensity after passing through a medium of length  $l$ , and  $\tau$  the turbidity coefficient of the medium. Equation [1] ignores losses of light through true absorption by suspended particles or reflection from the sides of the sample container.

### Light-Scattering Theory and the Influence of Particle Size

Appropriate light-scattering theory is governed by the diameter,  $D$ , of the scattering elements in relation

**Figure 1** Influence of particle size on the angular distribution of scattered light: (A) small particles ( $D < 0.1\lambda$ ); (B) large particles ( $D \sim 0.25\lambda$ ); and (C) larger particles ( $D > 1\lambda$ ). (From Vanous RD, Larson PE, and Hach CC (1982) *The theory and measurement of turbidity and residue*. In: Minear RA and Keith LH (eds.) *Water Analysis*, vol. 1, pp. 163–234. New York: Academic Press.)

to the wavelength,  $\lambda$ , of the light emitted by the measuring instrument. Indeed, theory is often specified in terms of the Mie size parameter ( $\alpha = 2\pi R/\lambda$ ), where  $R$  is particle radius. Particle size thus forms an appropriate basis for the subdivision of the theoretical discussion that follows.

### Small Particles

For particles where  $D < 0.05\lambda$ , Rayleigh scattering theory of 1871, originally developed for gases, is applicable to liquids with low concentrations of suspended particles which do not interact with each other. For such small particles, relatively symmetrical light-scattering distributions are obtained (Figure 1A). If a visible light source (i.e.,  $\lambda = 0.4\text{--}0.7\ \mu\text{m}$ ) is employed, then it follows that this theory is applicable for particles where  $D < \sim 0.03\ \mu\text{m}$ .

The Rayleigh equation describing the angular distribution of resultant scattering is:

$$i_\theta/I_0 = \{(n'/n) - 1\}^2 (NV^2/\lambda^4 r^2)(1 + \cos^2 \theta) \quad [2]$$

where  $i_\theta$  is the intensity of light scattered at angle  $\theta$ ,  $I_0$  is the initial light source intensity,  $n'$  is the refractive index of the particles,  $n$  is the refractive index of the suspension medium,  $r$  is the distance from the particles to the point of measurement, in terms of the number,  $N$ , of particles, each of volume  $V$ . Rayleigh's work thus shows that the intensity of scattered light varies: (1) with the square of the particle volume – and thus with the sixth power of the particle radius, assuming spherical shapes; and (2) inversely with the fourth power of the light wavelength used. Rayleigh theory has since been developed to allow relative molecular masses and sizes to be determined.

### Large Particles

For larger particles, however, where  $0.1\lambda < D < 0.8\lambda$ , the angular distribution of scattered light becomes asymmetrical. Destructive interference of light scattered in the backward direction leads to a bias in forward-scattered light (Figure 1B). In these contexts, Mie scattering theory of 1908 for larger spheres becomes more appropriate. For such larger

**Figure 2** Influence of sediment particle diameter on light absorbance by samples of different concentrations. Note how a given concentration effects much greater absorbance at the smaller particle diameters. (Reproduced with permission from Ward PRB and Chikwanha R (1980) *Laboratory measurement of sediment turbidity*. *Proceedings of the American Society of Civil Engineers, Journal of the Hydraulics Division* 106: 1041–1053.)

particles, scattering intensity is less dependent on wavelength.

### Very Large Particles

For larger particles still, where  $D > 0.8\lambda$ , the Mie equations are still workable, although for particles larger than  $\sim 0.4\ \mu\text{m}$  in diameter wide oscillations in scattering patterns emerge. For particles of  $D > 1\ \mu\text{m}$ , extreme concentration of scattering in the forward direction emerges (because of mutually destructive backscattering effects), along with secondary peaks in the angular distribution of scattered light (Figure 1C).

Theory and practice also demonstrate that the most efficient scattering elements are those of a diameter similar to the light wavelength used. Also, a given mass of small particles causes much greater light attenuation than the same mass of large particles (Figure 2).

One complexity is that much classical theory has been developed for identically sized spherical particles – conditions that may not be obtained in all laboratory or field situations. Indeed, many natural

waters, like the atmosphere, contain an ensemble of variably sized, irregularly-shaped, and randomly oriented particles, for which theory is still being developed. Furthermore, processes become highly complex when concentrations are so great that multiple scattering occurs (i.e., particles receive light previously scattered from other particles: this normally increases opportunities for light absorption).

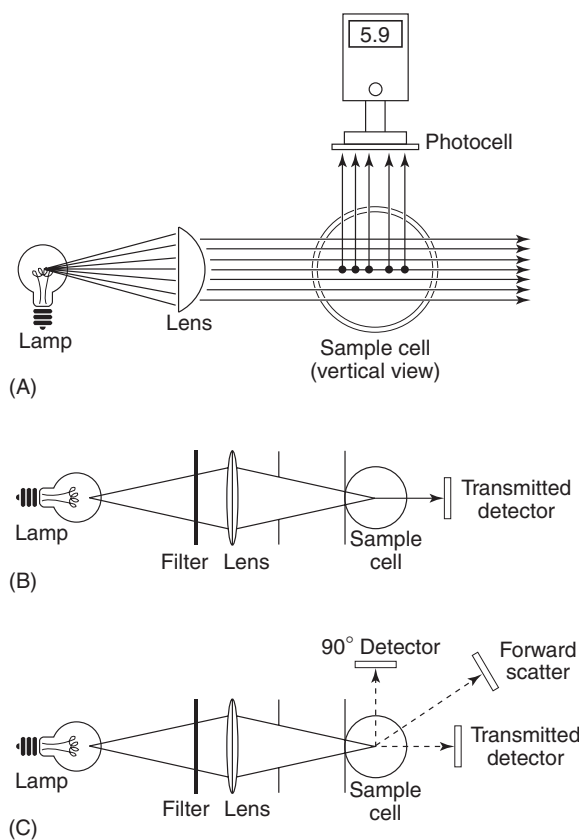

## Instrumentation

### Range of Turbidimetric and Nephelometric Systems

Early procedures were based on manual operation of analytical systems and visual turbidity assessment (e.g., the Secchi disk). Several instruments are now available, however, for quantitative turbidity determination in a variety of scientific, industrial, and process management applications. Choice will depend largely on the analytical aims (e.g., mass concentration, particle size distribution, molecular dimensions, or crystal/cell growth), the nature of the scattering elements and suspension medium, and whether field or laboratory measurement is needed. Turbidimeters also vary in optical geometry, mode of operation, sample handling capabilities, data recording options (e.g., automatic/manual or analogue/digital) and portability. Ultraviolet-visible spectrophotometry can also be used for turbidimetric measurements by measuring the absorption of light by particles at a fixed wavelength or full spectrum (e.g., for kinetic studies of the time decay of species). The discussion that follows focuses on the use of turbidimetric instrumentation to estimate the mass concentration of suspended matter in liquid samples, with particular reference to sediment in natural waters.

### Basic Elements of Measurement Systems

Modern measurement devices use photosensitive cells to quantify scattered and/or transmitted light. Figure 3 illustrates that most laboratory bench instruments usually have five basic components: a light source of known, constant intensity, and given wavelength characteristics; a lens to collimate the light beam; a sample cell; photosensor(s); and a meter or logger to record the output signals from the photosensor(s). Versions for continuous monitoring of turbidity values (e.g., for online industrial systems or process measurement in environmental sciences) include some kind of flow-through measurement chamber (instead of a 'static' sample cell) and outputs for a datalogger. The two basic measuring instruments are the nephelometer and the turbidimeter.

**Figure 3** Three basic designs of turbidity meter: (A) the nephelometer, which directly measures light scattered (usually at 90° to the beam direction) by suspended particles; (B) the turbidimeter, where the transmitted light is detected, in relation to initial beam intensity; (C) the ratio turbidimeter in which both transmitted and scattered light is detected. (Reproduced with permission from Hach CC, Vanous RD, and Heer JM (1982) Understanding turbidity measurement. *Technical Information Series*, Booklet No. 11, 1st edn., 11pp. Hach Chemical Co.)

A 'nephelometer' measures directly the intensity of light scattered by the sample, which is proportional to the amount of matter suspended in the light path, though the influence of size, shape, and refractive index of the scattering particles is also important. With nephelometers, the sensor is mounted at an angle to the traversing beam (often 90°) to record scattered light in one part of the angular distribution (Figure 3A). Some more sophisticated versions can monitor scattering intensity at many different angles: this allows angular summation values to be checked against initial and attenuated signals. Nephelometers usually provide better precision and sensitivity than turbidimeters and are normally used for samples of low turbidity containing small particles.

A 'turbidimeter', sometimes called a transmissometer, absorptiometer, or turbidity meter (the latter term is commonly used for field instruments in the earth and environmental sciences), measures the

intensity of the beam after it has passed through the sample, i.e., it quantifies the amount of transmitted light remaining (**Figure 3B**). Suspended matter in the light path causes scattering and absorption of some light energy, which reduces the incident illumination falling on the photocell. These instruments are more appropriate for relatively turbid samples in which the scattering particles are large in relation to the light wavelength used. This is because a significant reduction in the intensity of incident light is needed to yield precise results.

Some newer instruments, called ratio turbidimeters, incorporate measurement systems for light which is side-scattered (usually at  $90^\circ$ ), forward-scattered, and transmitted (**Figure 3C**). The turbidity value is obtained as the ratio of the  $90^\circ$  signal to the sum of forward-scattered and transmitted values. The ratio feature has a number of advantages: it increases the long-term stability of the sensor (by reducing effects of instrumental drift); it compensates for ageing of, and deposits on, the optics; it reduces the influence of temperature changes in the electronics; it minimizes the need for repeated recalibration; and it limits the effect of sample color on readings. This can be more appropriate for strongly and/or variably colored liquids, or for samples of high turbidity. A four-beam instrument version has emerged recently, which reduces error still further.

Recent developments include laser-based turbidimeters, reflectometers, or fiber-optic systems. The development of the optical backscatter sensor (OBS) has become popular for field deployment in the hydrological and oceanographic sciences: this instrument monitors water turbidity through the backscattering of pulsed infrared light emitted from the OBS instrument head. Also, remotely sensed turbidity measurement, using satellite or air borne instruments (e.g., the CASI (Compact Airborne Spectrographic Imager) system deployed by the UK Natural Environment Research Council), has recently eased the mapping of turbidity patterns over large spatial scales.

There is a strong dependency of scattering efficiency on light wavelength (see above). Consequently, for a given detector, light sources of short wavelength are more sensitive to, and therefore more useful for, the detection of small particles. Conversely, longer wavelengths are more appropriate for samples containing large particles (e.g., sediment in many earth or environmental science systems). The source-detector relationship can vary widely between instruments, and is cited as the key reason explaining the different readings obtained on the same sample by different devices.

## Units of Measurement and Instrument Calibration

The field is hampered by a nonstandard, ill-defined, and historically changing unit of measurement. The Nephelometric Turbidity Unit (NTU) is the most common unit employed. The precision with which turbidity data should be reported depends on how turbid the sample is, but should be to the nearest 1–10%, approximately, of the NTU value determined. For example, NTU values for distilled water, tap water, and raw water are 0.08, 0.54, and 3.52, respectively, but much higher values, well above 150 NTU, are common in many hydrological systems.

Formazin polymer, developed in 1926, can be used for turbidimeter calibration, and is straightforward to prepare, control, and reproduce. Standard procedures for the production of a stock formazin turbidity suspension of 400 NTU are given in American Public Health Association. Other calibration materials can be used (e.g., Fullers Earth or Hach Gelex 'fixed' standards – metal oxide particles permanently and statically suspended in silica gel) and may provide suitable alternatives, especially given the health concerns voiced in some quarters over formazin use.

## Field Calibration

In natural waters, suspended material may largely consist of particles in the size range of clay ( $D < 2 \mu\text{m}$ ), silt ( $2 < D < 63 \mu\text{m}$ ), or even sand ( $63 < D < 2000 \mu\text{m}$ ). It may also include organic matter and compounds and microscopic organisms. For field applications in hydrology or oceanography, analysts should preferably calibrate turbidity readings against known mass concentrations of the suspended sediment typical of that context, and declare the strength of the diagnostic statistics for derived relationships. Such correlations can be weak, reflecting temporal changes in suspended load composition (and hence its light-scattering efficiency), water color, or bubble presence. Predictive relationships can be strengthened by accounting for such changes (especially in sediment load particle size distribution), which can occur over various timescales (e.g., interannual, seasonal, subseasonal, flood event). It may even be necessary to produce multivariate or separate calibration equations to incorporate the effects of, for example, changing flow levels, sediment source areas, and season on sediment load constitution. For such field applications, the turbidimeter reading (often in arbitrary units) is converted to estimated SSC using a site-specific calibration curve.

### Turbidity Meters for Continuous Field Operation

For unattended automated field use a range of suitable turbidity meters with additional instrumental features are available. The measurement cell is replaced by a flow-through chamber, which must prevent stray light from reaching the photosensor. Instruments can be boom-mounted directly in the flow, or at the end of pump-lines connecting sampling point to measurement system.

Turbidity meters with narrow-band near infrared (NIR) light sources (peak output at  $0.86\ \mu\text{m}$ ; spectral bandwidth  $<0.06\ \mu\text{m}$ ) are recommended by ISO. Such instruments reduce problems of algal build-up on the optical surfaces, are less affected by color, and are more sensitive to the slightly larger particles typical of sediment transport systems. However, some relaxation of the infrared protocol is tolerable for field instruments operating in continuous monitoring mode.

To limit further the impact of problematic algal growth on the optics, field turbidimetric systems can be equipped with a pulsed light source, antifouling chemicals or films, and/or 'wiper' blades for convenient (sometimes automated) cleaning of optical surfaces. Alternatively, a dual-beam (twin-gap) instrument to compensate for these effects can be deployed.

Power requirements for field instruments are important considerations. The use of low-consumption light-emitting diodes (LEDs) in sensors, and photovoltaic sensors which convert incident light directly into electrical energy, reduces power needs to a minimum. Solar panels are useful to trickle-charge instruments and dataloggers.

Some instruments are temperature sensitive, largely because LEDs can emit more strongly when warm, and photovoltaic detectors convert photons into electrons more efficiently at low temperatures. Given, for example, the annual range of river temperature in the UK is typically  $\sim 20\text{--}25\ \text{K}$ , some correction procedures may be necessary.

Figure 4 also demonstrates that many turbidity meters are relatively insensitive to very fine or very coarse particulate matter. Because most instruments work in the visible or NIR spectrum this means that the most readily detectable particles are those where,  $\sim 0.2 < D < 1.8\ \mu\text{m}$ . In standard sedimentological and engineering classifications, these are clay-sized particles, and hence the occasionally used term 'silt-meter' for turbidimetric instruments is not entirely appropriate.

Turbidity meters need to be interfaced with portable multimeters, dataloggers, or computers for recording and storage of turbidity data. Dataloggers

**Figure 4** Sensitivity of two turbidity meters to particle diameter (HF = H.F. instruments). Test material here is spherical latex particles of very narrow size distribution. (From Vanous RD, Larson CC (1982) The theory and measurement of turbidity and residue. In: Minear RA and Keith LH (eds.) *Water Analysis*, vol. 1, pp. 163–234. New York: Academic Press.)

equipped with an appropriate input channel and needing minimal power for operation are heavily used today. They provide quasi-continuous digital data on temporal variations in turbidity, which are ideal for computational analysis and the study of turbidity dynamics. Telemetry systems for real-time data acquisition, alarm facilities, and remote downloading capabilities are becoming increasingly common.

Many field scientists, however, despite the range of commercially available turbidity instrumentation, still recognize a need for low cost, rugged, and reliable systems. This is especially so when a network of instruments is required for permanent installation to define a turbidity field, for simultaneous manual turbidity measurements by a research team, or for specialist applications such as in subglacial environments. This has led many researchers to custom-build their own instruments.

### Hydrological Applications of Turbidimetry

The monitoring of turbidity and SSCs in rivers, estuaries, lakes, reservoirs, nearshore zones, etc. is attracting increasing attention from hydrologists, limnologists, geomorphologists, freshwater ecologists, engineers, oceanographers, glaciologists, water resource managers, and policy makers. Such measurement programs can allow inferences to be made about upstream hydrogeomorphological processes,

catchment erosion rates, downstream fluvial processes and sedimentation impacts, pollutant and contaminant transfer, and aquatic habitat quality. The recreational value of water bodies can be partly linked to their clarity, as demonstrated in the Lake Tahoe turbidity reports of 2001–02. Increasingly, there is a legal requirement for environmental impact assessments and water supply managers to consider the possibility of short- or long-term turbidity increases resulting from proposed development schemes.

Automated, in-stream, high-frequency turbidity monitoring has become increasingly popular, mainly because the alternative practice of sampling and subsequent laboratory processing of samples is laborious and resource-intensive. Sampling approaches thus inevitably constrain the level of temporal and spatial detail possible, making it difficult to reveal the patterns, dynamics, and processes present. Recent advances in the understanding of the hydrodynamics of fine-sediment transport in river, tidal, and nearshore environments, for example, would have been impossible without very high frequency (e.g., 5 Hz) monitoring of transient turbidity changes. In remote environments, and in the developing world, a likely paucity of suitable sample analysis facilities underlines the need for an automated and direct field-based method.

Three example applications of continuous monitoring are outlined below: river turbidity variation during rainstorms; very short-lived turbidity pulsing in glacial and coastal waters; and the definition of the estuarine turbidity maximum. These illustrate the many advantages of turbidity instrumentation over sampling-based approaches in quantifying and understanding complex temporal and spatial patterns of suspended sediment fluxes. They also demonstrate the substantial variations of turbidity and SSCs in natural systems in space and time.

### River Turbidity Variation through Individual Storm Events

SSC in streams can change appreciably over seasonal timescales and during high-flow events. Automated river turbidity monitoring is very useful in refining calculations of suspended sediment loads, because it detects the short-lived, but very important order-of-magnitude changes in SSC that occur in many rivers during complex storm events (e.g., **Figure 5**). The 1-min datalogging scan interval used in **Figure 5** defined all peaks and troughs in turbidity for most events. Following calibration, this permitted the full definition of exhaustion phenomena in SSCs, and

**Figure 5** Continuous record of stream suspended sediment concentration, in relation to river discharge changes during storm events, derived from calibration of a Partech turbidity record. (From Gippel CJ (1989) The use of turbidity instruments to measure stream water suspended sediment concentration, Monograph Series No. 4, Department of Geography and Oceanography, University College, University of New South Wales, Australian Defence Force Academy, Canberra, 204pp.)

hysteresis effects in relation to the discharge series (hitherto undetected for the system by earlier workers using a conventional sampling program). This led, in turn, to more securely based explanations of fine-sediment delivery processes.

### Turbidity Pulsing in Rivers and Nearshore Zones

Turbidimetric instrumentation also facilitates the detection of very short-lived pulsing of suspended sediment, which characterizes many systems, especially proglacial meltwater environments. The example in **Figure 6**, for the Jökulsá á Sólheimasandi glacial river in southern Iceland, shows two substantial sediment-pulsing events detected by a 2-min turbidity scanning program. These were unrelated to river flow variations, and showed that other significant sediment mobilization processes were present in the system. The alternative approach of flow-triggered automated sampling is unsatisfactory in these situations where many sediment-flux perturbations are unrelated to water discharge.

One strength of automated turbidity monitoring is that the logging system can also be used to record, on the same time base, data on associated or explanatory variables. For glacial meltwater studies (**Figure 6**), these typically include energy budget components relevant to glacial ablation, rainfall intensity, river discharge, temperature, and electrical conductivity, and, with Photo-Electronic Erosion Pin (PEEP) sensors, even the erosion events themselves which generate sediment plumes. Such data can strengthen the

**Figure 6** Two-minute scanning of turbidity and river discharge (8–9 Aug 1988) showing a compound pulsing of suspended sediment concentration, unrelated to flow variations, in the Jökulsá á Sólheimasandi glacial river in southern Iceland. (Reproduced with permission from Lawler DM and Brown RM (1992) A simple and inexpensive turbidity meter for the estimation of suspended sediment concentrations. *Hydrological Processes* 6: 159–168; © John Wiley and Sons Ltd.)

**Figure 7** A high-frequency, 5 Hz, 10-min time series of OBS turbidity alongside river flow components ( $u$ , streamwise;  $v$ , normal to the bed) for the Fraser River, near Mission, BC, Canada. (Reproduced with permission from Lapointe M (1992) Burst-like sediments suspension events in the sand bed river. *Earth Surface Processes and Landforms* 17: 253–270; © John Wiley and Sons Ltd.)

process-inference capabilities of the whole exercise. Thus, the correlation of high-frequency velocity and OBS turbidity series (Figure 7) allowed a clearer understanding of river sediment transport events to be gained. In coastal zones, very high frequency (5 Hz) monitoring of OBS turbidity, wave height, and currents (Figure 8), facilitated the definition of the critical flow velocities required to mobilize bed sediment. Knowledge of these threshold conditions is important for the stability, engineering, and protection of coastlines and their ecosystems.

### Estuarine Turbidity Maxima

The ‘estuarine turbidity maximum’ is the term given to the clear peak in mean SSC observable in many estuaries around the limit of saline intrusion. Improved explanations of turbidity fields in estuarine systems, including the nature, location, and migration of the turbidity maximum, and the tidal pumping processes responsible, have recently been obtained by supplementing water sampling approaches with detailed automatic turbidity monitoring. Furthermore,

**Figure 8** A high-frequency, 5 Hz record averaged to hourly time series of OBS turbidity (SSC), in relation to significant wave height,  $H_s$ ; cross-shore current,  $U$ ; and longshore current,  $V$ , for the North Sea nearshore zone at Holderness, UK. Data from Feb. 1996; water depth 16.8 m. The OBS here has been deployed within BLISS (Boundary Layer Intelligent Sensor System). (From Blewett J and Huntley D (1999) Measurement of suspended sediment transport processes in shallow water off the Holderness coast, UK. *Marine Pollution Bulletin* 37(3–7): 134–143.)

**Figure 9** Relationship between estuarine turbidity in NTU and distance from the mouth of St. Lucia Estuary, Natal, on a rising tide on 20 March 1981, showing a clear turbidity maximum ~8–12 km from the estuary mouth for both near-bed (bottom) and surface (top) waters. for any spatial survey, the fact that turbidity values are obtained at the field sites themselves, rather than in the laboratory subsequently, can allow instant decisions to be made regarding any further environmental sampling (including turbidity) that may be desirable. **Figure 9** illustrates the value of repeated estuarine turbidity measurement in revealing the spatial and temporal structure of the turbidity maximum.

## Inorganic Compounds

**M A Zezzi-Arruda and R J Poppi**, University of Campinas, Campinas, Brazil

## Introduction

Spectrophotometry is an excellent alternative for the determination of inorganic compounds. It is characterized by a wide analytical working range,

and therefore sample dilution is avoided. Versatility, low cost, easy implementation, etc. are in general inherent to this technique. Plug-and-play equipment is often used. These characteristics make spectrophotometry one of the most versatile of analytical techniques.

Further, the nature of the reagents used in spectrophotometric applications, used in catalytic procedures or to form complexes, allows chemical reactions involving mixed ligand and ion-association systems, organized media, etc. to be carried out to determine different analytes, thus increasing the applicability of spectrophotometry.

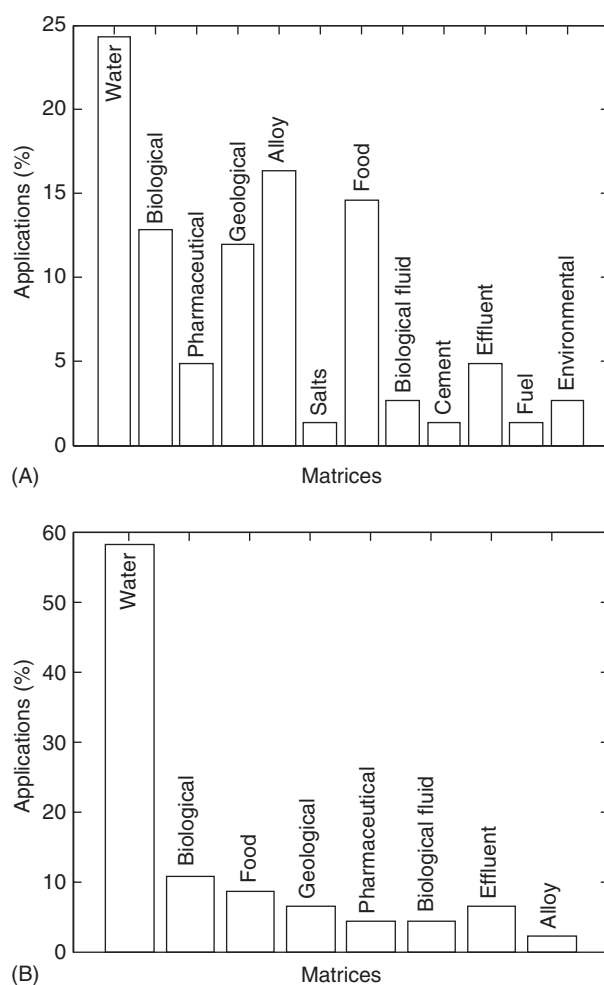

The majority of spectrophotometric applications are related to inorganic compounds. Hundreds of combinations can therefore be found, thus making it possible to determine one analyte, for example, using different spectrophotometric reagents.

In view of the wide spectrum of reagents, analytes, applications, systems, and their combinations involved, this article was written to inform readers about the reagents used in spectrophotometric analysis, with emphasis on inorganic species (cationic and anionic) because of their importance in analysis and to provide examples found in the literature, mainly from 1998 onwards. **Figure 1** provides examples of applications of spectrophotometry in different areas, such as environmental, biological, and pharmaceutical applications. From this figure, it can be concluded that the majority of applications relate to water, alloy, and food samples in which cationic species are determined. For anionic species, once again, water was the main matrix analyzed.

## Cationic Species

### Aluminum

Reagents such as quinizarin, alizarine violet N, semi-xylol orange, Eriochrome cyanine R, alizarin yellow, and chrome azurol S are used for aluminum determination. These reagents tend to form different complexes with Al, sometimes leading to good sensitivity of the method (nanogram per milliliter detection limits using alizarine violet N) or increasing its selectivity, thus allowing aluminum determination in complex matrices such as cement (quinizarin), plant digest (chrome azurol S), milk (alizarin), and botanical samples (Eriochrome cyanine R). However, when the selectivity is still not enough to guarantee accurate results, different strategies such as the use of extraction techniques, exchange resins, or surfactants are used.

**Figure 1** Applications (%) of (A) spectrophotometric determinations of cationic species and related matrices and (B) spectrophotometric determinations of anionic species and related matrices.

### Boron

Classical reagents such as azomethine-H and curcumin are frequently used in boron determination. Azomethine-H is used, for example, in boron determination in plants, geochemical materials, and soils. Curcumin is used in determination of boron as an impurity in silicon-doped gallium arsenide used in electronics and in high-purity molybdenum. The microgram per gram limit of detection (LOD) is attained when curcumin or 4-methoxy-azomethine-H (420 nm) is used. However, boron is also determined by the formation of the macrobicyclic complex Fe(Nx) (3) (BOH) (2) in the nioxime-boric acid-Fe(II) system (447 nm).

Boron has also been determined using the surfactant system formed with curcumin and cetylpyridinium bromide at 560 nm. A good Beer's law range has been attained ( $\leq 3 \mu\text{g}/25 \text{ ml}$ ).

Sometimes a preliminary extraction of boron with organic reagent is necessary for improving the selectivity as well as the use of a specific resin.

### Cadmium

Cadmium is commonly determined using 4-(2-pyridylazo)resorcinol; however, other ligands have been proposed, such as butylrhodamin B (607 nm), *p*-acetylbenzenediazoaminoazobenzene (475 nm), 2-pyridinediazoaminoazobenzene (530 nm), 5,10,15,20-tetrakis(4-carboxylphenyl)porphyrin (423 nm), and *meso*-tetra(4-trimethylammonium phenyl)porphyrin (434 nm).

A new azoamino reagent has been proposed recently for cadmium determination in wastewater, which at a pH value of 10.4 ( $\text{Na}_2\text{B}_4\text{O}_7/\text{NaOH}$  buffer) produces an orange-red chelate with cadmium (1:2, M:L) at 520 nm.

Some surfactants such as Triton X-100, OP emulsifier, and polyvinyl alcohol are commonly used to make some reagents soluble so that solutions can be prepared.

Cadmium is sometimes determined together with other metals such as zinc, lead, and mercury. Generally, these applications are based on the formation of metal-ligand complexes, and some kinds of statistical or chemometric tools (full factorial designs, sequential experimental Doehlert designs, artificial neural network, partial least square) are used for distinguishing the concentrations of each analyte. In addition, some applications are based on the kinetic differentiation of the reactions related to metals and the same ligands.

Problems with possible interferences are avoided by using either different masking agents such as picolinic acid, potassium cyanide, and potassium sodium tartrate or some kind of separation procedure.

Different samples are analyzed, independent of the chromogenic reagent used, such as beverages, powdered corn, powder milk, natural water and wastewater, nutritional supplements, fertilizers, lobster, and soya bean.

### Chromium

For chromium determination, reagents other than the classical 1,5-diphenylcarbazide, such as xylene cyanol FF (615 nm), *p*-amino-*N,N*-diethylaniline (550 nm), benzooxazol (538 nm), benzothiazol (546 nm), dimethylindocarboxyanine (560 nm) and dimethylindodicarboxyanine (640 nm), have been used.

Sometimes Cr(VI) is determined after sample preparation ( $\text{HNO}_3/\text{H}_2\text{SO}_4 + \text{KMnO}_4$  as oxidizing agent) by reacting chromium with 1,5-diphenylcarbazide. Determination of Cr(III) and Cr(VI) is also

emphasized nowadays. The general procedure for chromium speciation is carried out by determining Cr(VI) and total chromium. So the Cr(III) concentration is calculated as the difference between the Cr(VI) and total chromium values. In general, the reagent 1,5-diphenylcarbazide is commonly used for this task. However, other reagents have also been proposed: Cr(VI) reacts almost completely in a short period with *p*-amino-*N,N*-diethylaniline. Thus, Cr(III) is masked by cyclohexyldiaminetetraacetic acid and only Cr(VI) is determined. On the other hand, the sum of Cr(VI) and Cr(III) is determined after oxidation of Cr(III). From the difference between these two results it is possible to establish the Cr(III) concentration.

Complex samples are involved in chromium determination, such as industrial wastewater, natural water, pharmaceuticals, and soil, irrespective of the strategy adopted.

### Cobalt

Different chromogenic reagents have been proposed for cobalt determination, such as 2-(5-bromo-2-pyridylazo)-5-(*N*-propyl-*N*-sulfoethylamino) aniline (550 nm), 1-(2-thiazolylazo)-2-naphthol (572 nm), *N,N'*-bis(2-aminobenzoyl) ethylenediamine (470 nm), isonitroso-5-methyl-2-hexanone (400 nm), 1-(2-pyridylazo)-2-naphthol (650 nm), 4,5-dihydroxy-1,3-benzenedisulfonic acid, disodium salt (426 nm), and pyridixal-4-phenyl-3-thiosemicarbazone (450 nm). In addition, a new reagent has been proposed for this task, 5-(6-methoxy-2-benzothiazoleazo)-8-aminoquinoline (MBTAQ), which presents an apparent molar absorptivity of  $1.15 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$  at 655 nm. In general, the molar absorptivity of the reagents used for cobalt determination ranges from  $10^4$  to  $10^6 \text{ l mol}^{-1} \text{ cm}^{-1}$ . However, some strategies are adopted for improving the LOD of these methods, such as the use of mechanized monosegmented flow systems (LOD nanogram per liter range), micellar media (LOD microgram per liter range), solid-phase spectrophotometry (LOD microgram per liter range), and preconcentration (LOD microgram per liter range).

A wide range of samples have been analyzed using complex formation with chromogenic reagents, micellar media, and catalytic reactions, among others, such as pharmaceutical, biological, and environmental samples, alloys, and industrial effluents. In addition, there are some chemometric applications, mainly those involving multivariate calibration.

### Copper

Some copper determination applications involve the use of organic solvents or surfactants such as

ethanol, Tween 80, sodium dodecyl sulfate (SDS), and Triton X-100. These are used to make the reagent more soluble or to improve reaction conditions. One example is the use of Triton X-100 in the DDTC-Cu<sup>2+</sup> reaction for spectrophotometric determination of copper in fungicides and fertilizers and a fourfold expansion in dynamic range has been attained.

Classical reagents such as 1-nitroso-2-naphthol, 1-(2-pyridylazo)-2-naphthol, 2-carboxy-2'-hydroxy-5'-sulfopharmazilbenzene are used for copper determination. In addition, they are also used for comparison with the results obtained with other reagents. Besides these reagents 4,5-dimercapto-1,3-dithiol-2-tionate (430 nm), 5,8-dihydroxy-1,4-naphthoquinone (330 nm), mercaptosuccinic acid (345 nm), di-2-pyridyl ketone benzoylhydrazone (370 nm), 5-mercapto-3-phenyl-1,3,4-thiadiazole-2-thione (395 nm), and others have also been proposed for this task. In addition, new reagents such as iminodibenzyl and 3-chloroiminodibenzyl (660 nm) or 3,3'-(1,3-propanediyl-diimine)bis-[3-methyl-2-butanone]dioxime (525 nm) have also been proposed for copper determination.

Different samples may be analyzed, jet fuels, soil and airborne dust particles, pharmaceuticals, alloys, dry tea, water, and industrial effluents, among others.

## Iron

Besides the classical chromogenic reagents commonly used for iron determination such as *o*-phenanthroline and Eriochrome cyanine R, others reagents have also been proposed for this task such as 4,5-dihydroxy-1,3-benzenedisulfonic acid, disodium salt (667 nm, Fe(III) determination), 1-(*p*-tolyl)-3-phenylpropane-1,3-dione (I) (520 nm, Fe(II) determination), 2-mercapto-3-pyridinol (640 nm, Fe(III) determination), *N,N*-dimethyl-*p*-phenylenediammonium dichloride (554 nm, Fe(III) determination).

Nowadays, the trend appears to be to determine simultaneously iron and other metals or Fe(II) and Fe(III) species. In the first case, some reagents such as 1,5-bis(di-2-pyridylmethylene)thiocarbonohydrazide, 2,4,6-tri-(2-pyridyl)-1,3,5-triazine are used. In the second case 4,5-dihydroxy-1,3-benzenedisulfonic acid, disodium salt (635 nm), 1-(5-bromo-2-pyridylazo)-2-naphthol-6-sulfonic acid (765 and 850 nm), azide complexes in tetrahydrofuran (396 nm), etc. are used

In simultaneous determination, some kind of resin or chemometric method (principal component regression) is used for improving the selectivity. For speciation, generally the same wavelength is used for determining different iron species. Sometimes

Fe(III) is determined first, and after using an oxidizing reagent, the total iron (Fe(II) + Fe(III)) is determined. So, by calculating the difference between the two results it is possible to establish the Fe(II) concentration.

Iron determination samples include pharmaceutical products, drinking and natural water, aluminum alloys, multivitamins, and infant milk products.

## Lead

For spectrophotometric lead determination the procedure normally used is the addition of sulfide to a solution, which results in the formation of a brown color due to the formation of colloidal lead sulfide. Ammonium, chloride, tartrates and citrates, as well as copper, bismuth, iron, and aluminum can cause interference.

Recently, highly sensitive and selective chromogenic reagents have been used for lead determination. Dibromo-*p*-methyl-methylsulfonazo, in phosphoric acid medium, reacts with lead to form a blue complex (642 nm). The limit of quantification (LOQ), LOD, and relative standard deviations (RSD) were found to be 7.30 and 2.21 ng ml<sup>-1</sup> and 1.1%, respectively. Dibromo-*p*-methyl-carboxysulfonazo, in a phosphoric acid medium, reacts with lead to form a blue complex (648 nm). The LOD and RSD were found to be 2.14 ng ml<sup>-1</sup> and 1.0%, respectively. *Meso*-tetra-(3,5-bibromo-4-hydroxyphenyl)porphyrin, in NaOH medium, reacts with lead to form a yellow complex (479 nm). The LOD, LOQ, and RSD are 0.70 and 0.21 ng ml<sup>-1</sup> and 1.0%, respectively. 2,5-Dimercapto-1,3,4-thiazole reacts with lead, in an acid medium, to produce a greenish-yellow chelate that absorbs at 375 nm.

A kinetic method has been developed to determine micromolar amounts of Pb(II) based on the catalytic effect of chromate in acidic media on the oxidation of mercaptosuccinic acid (420 nm and LOD of 20 µg l<sup>-1</sup>).

## Magnesium

There are two methods commonly used for magnesium determination. The first one is based on reaction, in sodium hydroxide media, with Titan Yellow (sodium salt of dehydrothio-*p*-toluidine sulfonic acid) to produce a colored red colloidal suspension. The other method is based on reaction with Solochrome Black to give a red soluble complex.

Magnesium(II) has recently been determined through complex formation with purpurin (PURP) at pH 9.5 (540 nm).

A method for simultaneous spectrophotometric determination of calcium and magnesium is based on

reaction with Eriochrome Black T at pH 10.1 and utilization of multivariate calibration. Also, this simultaneous determination has been accomplished by reaction of both analytes with methylthymol blue (MTB) in a strongly basic medium (610 nm). The magnesium was masked by 8-hydroxyquinoline for calcium determination alone.

A catalytic kinetic method is based on the inhibitory action of magnesium ions on the decoloration of the acid chrome blue K-Mn(II)-KIO<sub>4</sub> system at pH 11.9. The LOD is 7.6 ng l<sup>-1</sup>.

### Manganese

Usually, manganese is determined by oxidation to permanganate by periodate or persulfate (545 nm). New chromogenic systems have been recently proposed: 5,8-dihydroxy-1,4-naphthoquinone (naphthazarin) (695 nm), 9-phenyl-2,3,7-trihydroxy-6-fluorene with formation of a blue colored complex (591 nm), and *meso*-tetra(4-(carboxymethylenoxy)phenyl)porphyrin (TCMOPPH2) in the chromogenic system TCMOPPH2-Cd(II)-imidazole and *N,N'*-bis(2-hydroxy-5-bromobenzyl)-1,2-diaminopropane with formation of a brownish complex soluble in chloroform.

Another spectrophotometric method for determination of manganese oxide is based on the reaction of manganese with 1,2,4-trihydroxyanthraquinone (PURP) with an LOD of 68 ng l<sup>-1</sup>.

Kinetic spectrophotometric methods have also been used. The catalytic effect of manganese(II) on the oxidation of diphenylamine-4-azo-benzen-4'-sulfonic acid potassium salt with potassium periodate in the presence of 1,10-phenanthroline in weak media has been reported, with an LOD of 0.017 ng ml<sup>-1</sup>. A sensitive flow injection procedure is based on the catalytic effect of manganese on the oxidation of 2-2'-azinobis(3-thylbenzothiazoline-6-sulfonic acid) with periodate (415 nm).

### Molybdenum

Spectrophotometric determination of molybdenum can be accomplished by reaction with thiocyanate in an acid medium in the presence of tin(II) chloride (465 nm). Toluene-3,4-dithiol, usually referred to as dithiol, can also be used as a spectrophotometric reagent for molybdenum determination. In an acid medium, it forms a green complex that can be extracted using organic solvents.

A new selective and rapid method for the determination of molybdenum is based on reaction with Alizarin Red S in the presence of a water soluble polymer, poly(sulfonylpiperidinylmethylene hydroxide), which produces a red complex (500 nm). A new

sensitive and selective reagent, *p*-carboxyphenylfluorene, has been used for determination of molybdenum with measurements at 531 nm. The LOD of the method has been found to be 0.73 ng ml<sup>-1</sup>. Another new chromogenic reagent has been used, dimethoxyhydroxyphenyl-fluorone, which forms a red complex with molybdenum(VI) in the presence of Triton X-100 and a sulfuric-phosphoric acid medium.

Molybdenum can be determined using a kinetic spectrophotometric method based on the catalytic effect of molybdenum on the reduction of thionine by hydrazine monochloride in an acid medium. The reaction is monitored at 605 nm due to the decrease in absorbance of thionine.

### Nickel

The most usual method of spectrophotometric determination of nickel is using the reaction with dimethylglyoxime and an oxidizing agent (bromine, for example) in alkaline solution to form a red soluble complex (445 nm).

Novel sensitive and selective chromogenic reagents have been reported for nickel determination. A new thiazolylazo reagent, 2-(2-(5-methylbenzothiazolyl)-azo)-5-dimethylaminobenzoic acid in the presence of SDS, forms a blue-violet complex (640 nm). Azocalix(4)arene, 5,17-bis(quinolyl-8-azo)25,26,27,28-tetrahydro-xycalix(4)arene reacts with nickel in a basic medium (580 nm), with an LOD of 1.4 × 10<sup>-7</sup> mol l<sup>-1</sup>. MBTAQ, in the presence of cationic surfactants and a borax buffer solution, forms a blue colored complex with nickel. The LOD of this methodology is 45 ng l<sup>-1</sup>. Another reagent is *o*-carboxylbenzenediazoaminoazo benzene, which reacts with nickel to form a complex (540 nm) at a pH of 10, and the method has an LOD of 0.22 ng ml<sup>-1</sup>. Iminodibenzyl and 3-chloroiminodibenzyl are also used for nickel determination. The reaction is carried out in a neutral aqueous medium, and a blue complex (660 nm) is formed. Finally, another reagent used is di-2-pyridil ketone benzoylhydrazone, in which the yellow Ni(II) complex presents a maximum absorbance at 406 nm.

### Selenium

Trace amounts of selenium can be determined using its reaction with potassium iodine in an acid medium to liberate iodine. The liberated iodine can react with starch to form a blue colored species (570 nm) or can bleach the violet color of thionin (600 nm). This method can be used for the determination of selenium in water, soil, plant materials, human hair, and biological samples.

Several kinetic spectrophotometric methods have been developed for selenium determination. The catalytic effect of Se(IV) on the reduction of thionine by sulfide ions has been explored. The reaction is monitored spectrophotometrically by following the decrease in absorbance at 598 nm, and the method has an LOD of  $5 \text{ ng ml}^{-1}$ . Another method is based on the catalytic effect of selenium on the oxidation of methyl yellow by hydrogen peroxide in a nitric acid medium. It is monitored by the loss of the red color of methyl yellow. The method is extremely sensitive, with the possibility of measuring concentrations of  $0.2 \text{ ng ml}^{-1}$ . Selenium can be also determined based on its effect on the oxidation reaction of methyl orange with bromate in acidic media.

### Vanadium

There are two commonly used spectrophotometric methods for vanadium determination. The first one involves the reaction of peroxide with vanadium(V) in sulfuric acid media, producing a reddish-brown coloration due to the formation of vanadyl sulfate (450 nm). The second method is based on the reaction of phosphoric acid and sodium tungstate with an acid vanadate solution. The product of these reactions is a yellow, soluble phosphotungstovanadic acid.

Several sensitive and selective methods have been proposed recently for vanadium determination based on different chromogenic reagents, such as 1,5-diphenylcarbohydrazine (1,5-diphenylcarbazine) in a slightly acid medium (531 nm), 2-(5-nitro-2-pyridylazo)-5-(*N*-propyl-*N*-sulfopropylamino)phenol in a weakly acid medium (592 nm), 2-(2-thiazolylazo)-*p*-cresol in the presence of ascorbic acid (525 nm), and 6-chloro-3-hydroxy-7-methyl 1-2-(2-thienyl)-4H-chromen-4-one in a weakly acidic medium (425 nm). Also, the utilization of 4-(2-pyridylazo)-resorcinol (PAR) in the presence of hydrogen peroxide (542 nm, LOD  $0.0028 \text{ } \mu\text{g ml}^{-1}$ ) and in the presence of cetylpyridinium chloride and ethylenediaminetetraacetic acid (600 nm, LOD  $3.0 \text{ } \mu\text{g ml}^{-1}$ ) has been proposed.

Vanadium has also been determined at 560 nm using a mixed ligand system with PAR and *N*-phenylbenzohydroxamic acid in steels and Ti alloys. With this system the linear range was  $\leq 2 \text{ mg l}^{-1}$ . Kinetic spectrophotometric methods have also been used for vanadium determination. These methods are based on the catalytic effect of vanadium in the following reactions: diphenylamine and hydrogen peroxide in a concentrated solution of formic acid (583 nm); oxidation of indigo carmine by bromate (612 nm); reduction of thionine by ascorbic acid at pH 5 (598 nm); Victoria blue B and potassium

bromate in the presence of citric acid and in a diluted sulfuric acid medium (618 nm); and oxidation of Nile Blue by bromate in an acidic medium (585 nm).

Applications related to vanadium determination and micellar media can also be found. Different oxidation states of vanadium have been determined at pH 5 using gallic acid in a cationic micellar solution of cetyltrimethyl ammonium bromide (CTAB).

## Anionic Species

### Fluoride and Chloride

Fluoride is generally determined in water and toothpaste because of its use in protecting teeth. Nowadays, there are different strategies for determining fluoride, such as the extraction-spectrophotometric method. In such methods, solid phase extraction is used for extracting fluoride from the sample (generally an aqueous matrix), and an organic solvent is used for eluting the analyte.

Besides classical reagents as Eriochrome cyanine and acid zirconyl (SPADNS), reagents such as alizarin complexone, MTB, and 2,4-diaminophenol have been proposed for fluoride determination.

Fluoride is generally determined by forming a complex with the reagents; it sometimes acts as a catalyst or inhibits chemical reactions. Example, fluoride ions form stable complexes with Fe(III), thus reducing its catalytic effect in the oxidation of 2,4-diaminophenol by hydrogen peroxide. In the other case, ternary complexes can be used for fluoride determination, such as that based on La(III)-F<sup>-</sup>-alizarin complexone (ALC).

The fluoride concentration range that can be determined by spectrophotometry generally is in the milligrams per liter range.

Regarding chloride, it seems that there are only a few applications in the literature related to its spectrophotometric determination. Classical reagents such as  $\text{HgC}_6\text{Cl}_2\text{O}_4$  or  $\text{Hg}(\text{SCN})_2$  continue to be used; however, recent examples of chloride determination are based on exchange complexation reactions proceeding in the system with immobilized diphenylcarbazone-mercury(II). Another recent application uses a mechanized system for chloride determination, and the reaction is based on the sequential introduction of mercuric thiocyanate/iron(III)/nitric acid. Generally the analytical work range is milligrams per liter, and samples such as mineral water have been analyzed.

### Nitrate/Nitrite

Reagents such as naphthol green B, gallocyanine (530 nm), pyrogallol red (465 nm), safranin O

(520 nm), and phosphomolybdenum (820 nm) have been used for nitrate/nitrite determination.

Some applications for determining nitrite are based on the decrease in colour of a complex. For examples, nitrite is determined by the oxidation of a phosphomolybdenum blue complex. Nitrite is then determined from the decrease in absorbance of the blue complex. The same analyte is also determined using its catalytic effect on the oxidation of gall-oceanine by bromate in acidic media and the decrease in absorbance of the system. However, when safranin O or resorcinol is used, the complexes formed are determined by an increased absorbance.

In the case of nitrate, the majority of applications for its determination are based on copperized-cadmium or cadmium-coated zinc reductor columns, which are generally used for reducing nitrate to nitrite. After formation of color, specific reagents are added and nitrate is determined from the difference between the total nitrite and nitrate concentrations.

Generally nitrate and nitrite are determined in samples such as natural water, soil, vegetables, and fish.

### Phosphate

Phosphate is spectrometrically determined using the molybdenum blue reaction. In this reaction, ortho-phosphate and molybdate ions condense in an acidic medium to form molybdophosphoric acid (or phosphomolybdic acid), which is reduced to produce a blue colored compound (molybdenum blue), measured at 830 nm.

Traces of phosphate ions can be determined by the reaction between molybdate, phosphate, and 3,3',5,5'-tetramethylbenzidine in an acidic medium to form a color charge transfer complex ion (458 nm). Another new approach for *ortho*-phosphate determination is based on the reaction of phosphate with the by-products of the oxidation reaction between diphenylamine and molybdenum(VI) in a formic acid solution medium (340 nm).

Generally silicate is a interference in the methodologies described previously. Methods have been developed for simultaneous determination of phosphate and silicate, based on kinetic information or using multivariate calibration. A kinetic separation method is based on the reaction of molybdenum blue and involves monitoring at different times. A multivariate calibration method proposed is also based on the reaction of molybdenum blue. Ascorbic acid and oxalic acid are added to the sample (molybdate/antimony) for the formation of two molybdate

complexes, and the spectra are recorded in the range 410–820 nm.

### Silicate

Silicate is determined by reaction with a solution of molybdate in an acidic medium to produce a complex molybdosilicic acid with a yellow color (400 nm). More accurate determinations are obtained by reduction of the complex to molybdenum blue (815 nm). Phosphates, arsenates, and germanates cause interference because they react with molybdate to produce complexes of the same color.

Silicate has also been determined based on the ion-association system formed with molybdate and rhodamine B. The proposed method has been applied to iron alloys, and the analytical range was up to 3.5 µg/50 ml with a wavelength of 585 nm.

As stated in the phosphate section, there are methods for simultaneous determination of phosphate and silicate.

### Sulfate

Sulfate is usually determined by reaction with barium chloroanilate at pH 4 to form barium sulfate and the acid chloranilate ion. At this pH value, the acid chloranilate ion is purple (530 nm). Another method is based on the formation of the  $\text{FeSO}_4^+$  cation (355 nm). An indirect method has been proposed based on the reduction of sulfate to sulfite with metallic sodium. The product is then reacted with iron(III) phenantroline to reduce iron(III) to iron(II), forming a red colored complex (515 nm).

### Introduction

Analysis of organic compounds not only encompasses functional group identification but also includes quantitative determination of trace amounts of hydrocarbons, organic solvents, heterocyclic materials, surface active agents, industrial chemicals like insecticides, fungicides, or drugs, and polymers and resins. This analysis assumes increasing importance in view of the widespread use of organic compounds in the pharmaceutical, clinical, industrial, and agricultural sectors. Further, the extreme toxicity of most of the organic compounds requires their critical monitoring in environmental, biological, geological, and industrial samples. This article presents ultraviolet (UV)–visible spectrophotometric approaches used for qualitative identification and quantitative analysis of organic compounds. Even though elemental analysis of physical properties including molecular weight determination, forms a part of organic compound analysis. These are not included in the present article. Rather, emphasis is given to quantitative trace analysis of organics either by direct determination or hyphenation techniques and chemometric approaches or by adopting suitable preconcentration procedures.

### UV–visible Absorption Spectra

The electromagnetic spectrum covers a wide range of energies (frequencies) and their wavelengths. Useful frequencies range from  $>10^{19}$  ( $\gamma$ -ray) to  $10^3$  Hz (radiowaves). The visible region, to which our eyes respond, is only a minute region of the entire spectrum. Such different types of radiation as gamma ( $\gamma$ )-rays or radiowaves differ from visible light only in the energy (frequency) of their photons. **Figure 1**

shows the regions of the electromagnetic spectrum that are used for spectroscopic analyses. The types of atomic and molecular transitions that result from interactions of the radiation with a sample are also shown. The energy level spacing of many molecules, especially large organic molecules, is such that they absorb light in the UV–visible wavelength range,  $\sim 190$ – $800$  nm. **Figure 2** shows visible spectra for 1,2,4,5-tetrazine that were obtained in vapor phase, hexane, and aqueous solutions. Many individual absorption peaks resulting out of transitions from the various vibrational and rotational states are clearly evident as the individual tetrazine molecules have separated from one another to vibrate and rotate freely. In the condensed state and in solution, however, the freedom to rotate is largely lost and rotational structure is rarely observed. Furthermore, frequent collisions and interactions with solvent molecules cause the vibrational levels to be modified energetically in an irregular way.

### Qualitative Organic Analysis

#### Direct Analysis

As stated above, the UV spectrum arises from electronic excitation ( $\sigma \rightarrow \sigma^*$ ,  $n \rightarrow \sigma^*$ ,  $n \rightarrow \pi^*$ ,  $\pi \rightarrow \pi^*$ ) of the molecule by the irradiating light. The energy required for the  $\sigma \rightarrow \sigma^*$  and  $n \rightarrow \sigma^*$  transitions is relatively high with absorption in the UV region, while the  $\pi \rightarrow \pi^*$  transition of electrons appears in the absorption in the UV–visible region. The important consequence is that the spectra in the UV region are diagnostic of unsaturation in the absorbing molecule. This comes about because with few exceptions only molecules containing multiple bonds have sufficiently stable excited states to give rise to absorption in the near-UV region. Thus, saturated hydrocarbons, alcohols, and ethers are transparent in this region. Further, monofunctional olefines, acetylenes, carboxylic acids, amides, and oximes have absorption maxima just outside the near-UV region ( $\sim 200$  nm) and in general show only end absorption.

Rather, emphasis is given to quantitative trace analysis of organics either by direct determination or hyphenation techniques and chemometric approaches or by adopting suitable preconcentration procedures.

### UV–visible Absorption Spectra

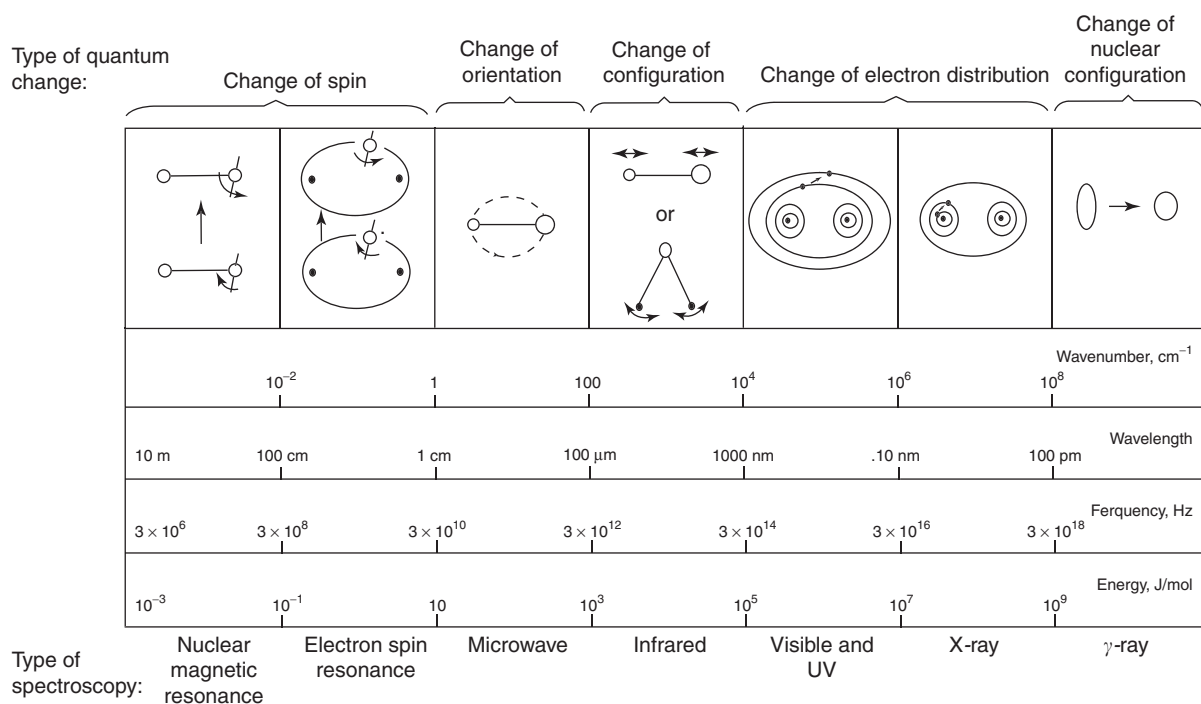

The electromagnetic spectrum covers a wide range of energies (frequencies) and their wavelengths. Useful frequencies range from  $>10^{19}$  ( $\gamma$ -ray) to  $10^3$  Hz (radiowaves). The visible region, to which our eyes respond, is only a minute region of the entire spectrum. Such different types of radiation as gamma ( $\gamma$ )-rays or radiowaves differ from visible light only in the energy (frequency) of their photons. **Figure 1**

shows the regions of the electromagnetic spectrum that are used for spectroscopic analyses. The types of atomic and molecular transitions that result from interactions of the radiation with a sample are also shown. The energy level spacing of many molecules, especially large organic molecules, is such that they absorb light in the UV–visible wavelength range,  $\sim 190$ – $800$  nm. **Figure 2** shows visible spectra for 1,2,4,5-tetrazine that were obtained in vapor phase, hexane, and aqueous solutions. Many individual absorption peaks resulting out of transitions from the various vibrational and rotational states are clearly evident as the individual tetrazine molecules have separated from one another to vibrate and rotate freely. In the condensed state and in solution, however, the freedom to rotate is largely lost and rotational structure is rarely observed. Furthermore, frequent collisions and interactions with solvent molecules cause the vibrational levels to be modified energetically in an irregular way.

### Qualitative Organic Analysis

#### Direct Analysis

As stated above, the UV spectrum arises from electronic excitation ( $\sigma \rightarrow \sigma^*$ ,  $n \rightarrow \sigma^*$ ,  $n \rightarrow \pi^*$ ,  $\pi \rightarrow \pi^*$ ) of the molecule by the irradiating light. The energy required for the  $\sigma \rightarrow \sigma^*$  and  $n \rightarrow \sigma^*$  transitions is relatively high with absorption in the UV region, while the  $\pi \rightarrow \pi^*$  transition of electrons appears in the absorption in the UV–visible region. The important consequence is that the spectra in the UV region are diagnostic of unsaturation in the absorbing molecule. This comes about because with few exceptions only molecules containing multiple bonds have sufficiently stable excited states to give rise to absorption in the near-UV region. Thus, saturated hydrocarbons, alcohols, and ethers are transparent in this region. Further, monofunctional olefines, acetylenes, carboxylic acids, amides, and oximes have absorption maxima just outside the near-UV region ( $\sim 200$  nm) and in general show only end absorption.

**Figure 1** The regions of the electromagnetic spectrum. The wavenumber, wavelength, frequency, and energy are the characteristics that describe electromagnetic radiation. (Reprinted with permission from Banwell C and McCash E (2003) *Fundamentals for Molecular Spectroscopy*. 4th edn. London: McGraw Hill; © The McGraw-Hill Companies, Inc.)

A third class of compounds comprising aldehydes, ketones, aliphatic nitro compounds, and esters is characterized by absorption maxima in the near-UV region. But they have intensities so low that they are useful only under special circumstances; i.e., acetone has a very low molecular extinction coefficient ( $\epsilon$ ) at its wavelength maximum of 270 nm. By way of comparison, a moderately strong bond would have an  $\epsilon$  of 1000–10 000  $\text{l mol}^{-1} \text{cm}^{-1}$ , and values as high as 100 000  $\text{l mol}^{-1} \text{cm}^{-1}$  are not uncommon. Table 1 lists some common chromophoric groups.

As seen from Table 1, UV spectroscopy would be limited severely if it is confined to monofunctional molecules. Fortunately, however, even functional groups such as the olefinic and carboxyl can give rise to strong absorption in the near-UV region when they are conjugated with one another. Thus, UV spectroscopy is a primary tool for the study of conjugated systems.

### Derivatization

Even though direct methods are often used for characterization of functional groups, in some instances, observation of the absorption spectra recorded after suitable derivatization leads to functional group identification. The types of reactions involved in such derivatization procedures include (1) formation

of azo compounds, (2) reaction with amines or phenols, (3) formation of nitro compounds, (4) formation of quinonoimino or polymethine compounds, (5) condensation of carbonyl compounds with various reagents, or (6) acidification of azomethines.

### Quantitative Trace Analysis of Organics Using UV-visible Spectrophotometry

Trace analysis refers to analysis for a minor component in a homogenous mixture. The definition of the term 'trace analysis' changes from time-to-time due to the rapid development of instrumentation or the use of sophisticated monitoring and measuring devices. By the current definition of the term 'trace component' proposed by the International Union for Pure and Applied Chemistry, the limit above which the term trace analysis can be used is 100 ppm ( $100 \mu\text{g g}^{-1}$ ). Microanalysis is a special case of trace analysis and is concerned with the analysis of a single small particle or a minor constituent in a heterogeneous mixture. Based on the analyte concentration in the sample to be examined, analytical methods and techniques are classified as below (see Table 2). The choice of analytical technique for a

**Figure 2** Typical ultraviolet absorption spectra of 1,2,4,5-tetrazine. (A) Gas phase spectrum where many lines due to electronic, vibrational, and rotational transitions are shown; (B) in a nonpolar solvent (hexane), where electronic transitions can be observed but the vibrational and rotational structures have been lost; and (C) in a polar solvent (water), where the strong intermolecular forces cause the blending together of the electronic peaks to give only a single, smooth absorption peak. **Table 1** Examples of some common chromophoric groups

Functional group	$\lambda_{\text{max}}$ (nm)	$\epsilon$ ( $\text{l mol}^{-1} \text{cm}^{-1}$ )
R-CH=CH-R	185	8000
R <sub>2</sub> C=O	270	16
R-COOH	204	41
R-CO-Cl	235	53
R-NO <sub>2</sub>	275	12
	210	1200
R <sub>2</sub> -S	229	10900
R <sub>2</sub> C=N-NH-CO-NH <sub>2</sub>	350	140
RN=NR	300	100
RN=O	670	20

given analysis depends on the primary criteria, such as sensitivity, selectivity, precision, and accuracy and auxiliary criteria such as speed, cost of the hardware, and special requirements, if any. Spectrophotometry in the UV and visible regions of the spectrum is one of the oldest analytical techniques and is still the most commonly used. At one time, the light intensity in the visible region was measured by visual

comparison with standards, but now absorbance is measured using sophisticated instruments, which provide greatly increased sensitivity and selectivity, the keys to trace analysis.

Quantitative analysis of organic compounds using UV-visible absorption spectra involves one of the following: (1) direct determination; (2) diazotization and coupling reactions; (3) formation of charge transfer complexes; (4) oxidation or reduction reactions; (5) formation of colored binary or ternary (ion-association) complexes; (6) catalytic procedures; (7) enzymatic reactions; (8) genomic, proteomic, and phonemic analyses; and (9) online analysis. Examples of each are given below:

**Direct determination:** Tannic acid, phenazone derivatives, human hemoglobin, piperine, thermolabile drugs, and drugs containing benzene ring chromophores have been determined quantitatively using direct UV spectral measurements.

**Diazotization and coupling reactions:** Diazotization and coupling reactions are used for, for example, trace determination of primary or secondary aliphatic alcohols and aromatic amines by employing UV-visible spectroscopy.

**Formation of charge transfer complexes:** UV spectral measurements of tranquilizers and antidepressants like chlorpromazine, promethazine, promazine, thioridazine, progesterone, imprimane, and amitriptyline, hydrazines, pyrazolones, and corticosteroid drugs resulted in their determination at trace levels via formation of charge transfer complexes.

**Oxidation or reduction reactions:** Based on the oxidation reactions of (1) phenothiazines with H<sub>2</sub>O<sub>2</sub> in acetic acid or KBrO<sub>3</sub>, (2) phenols with periodic acid, (3) catechol amines, adrenaline, noradrenaline, and isopropyl noradrenaline with ceric sulfate, and (4) compounds containing *cis*- $\alpha$ -glycollic and sulfide functional groups with periodate results in trace determination of organics using UV-visible spectrophotometry. The reduction of copper(II)-phenanthroline chelate to a colored Cu(I) complex allows the determination of aliphatic thiols using UV-visible spectrophotometry. Trace amounts of pharmaceuticals like  $\beta$ -lactam antibiotics, drugs like terbutaline, isoxsuprine, and vitamin B<sub>1</sub>, phenothiazines, and dissolved proteins and amino acids like tryptophan and tryosine have been determined based on the reduction of heteropoly acid into molybdenum blue followed by UV-visible spectrophotometry.

**Formation of colored binary or ternary (ion-association) complexes:** Binary complexes. Amino acids such as glycine, L-alanine, L-serine, L-phenylalanine,

**Table 2** Classification of analytical methods and techniques based on analyte concentration in a sample

S. no.	Analyte concentration	General name of analyte	Common term for analytical procedure	Examples
1	< 1 ppt ( $< 10^{-10}\%$ )	Submicrotrace component	Ultratrace analysis	Determination of dioxins in samples of various matrices
2	< 1 ppb ( $< 10^{-7}\%$ )	Ultramicrotrace component	Ultratrace analysis	Determination of trihalomethanes in drinking water and human urine. Determination of volatile organic compounds in indoor air
3	< 1 ppm ( $< 10^{-4}\%$ )	Microtrace component	Trace analysis	Determination of CO in ambient air
4	< 100 ppm (0.01%)	Trace component	Trace analysis	Determination of methane in ambient air
5	< 1%	Secondary component (admixture)	Semimicroanalysis	Determination of CO <sub>2</sub> in ambient air
6	1–100%	Primary component	Macroanalysis	Determination of carbon in coal dust

L-glutamic acid, and L-lysine have been determined spectrophotometrically using *p*-benzoquinone as the color-forming reagent. Ethyl violet is used as a chromogenic reagent for determination of anionic surfactants in mineral water and soft drinks using UV–visible spectrophotometry. A new color-forming reagent,  $\alpha,\beta$ -dinitrostilbene, has been used for UV–visible spectrophotometric determination of primary and secondary amines when these are sufficiently basic and sterically unhindered. Primary and aromatic amines can be determined by reacting them with syringaldehyde in a HCl–methanol medium using UV–visible spectroscopy. Similarly, sulfonazo III has been used for spectrophotometric determination of ascorbic acid. Reserpine, amidopyrine, diazepam, and other benzodiazepine tranquilizers can be determined by extraction of their binary complexes with alizarin violet 3B or alizarin brilliant violet R. Penicillins and cephalosporins have been determined by formation of 1:1 and 2:1 complexes with chloranilic acid during UV–visible spectrophotometric determination. Coomassie Brilliant Blue G can be used for trace determination of urine proteins, plant proteins, acid soluble proteins, and thermally denatured and insoluble proteins using UV–visible spectroscopy.

Ternary complexes. Traces of proteins have been determined spectrophotometrically by formation of colored ternary ion-association complexes with pyrogallol red and molybdenum(VI) or pyrocatechol violet and molybdenum(VI). Compounds containing the sulfydryl group were determined spectrophotometrically based on the extraction of their ternary ion-association complexes of rhodamine 6G and as-traphloxine cations with hexachloroantimonate(III) from buffered aqueous solutions into toluene.

Hydroquinone has been determined spectrophotometrically by reducing iron(III) to iron(II), which was extracted into chloroform as the ferroin–bromophenol blue ion-association complex.

**Catalytic procedures:** Ultratrace amounts of catalysts such as formaldehyde and oxime iodides can be determined by catalytic oxidation of Brilliant cresyl blue bromate and Mn(III)–As(III) reactions, respectively. Furthermore, determination of organic compounds is possible by exploiting their influence on reaction rates based on the activation or inhibition effects. Thus, endosulfan is determined based on its activation of the catalytic oxidation of caraminic acid by H<sub>2</sub>O<sub>2</sub>. On the other hand, ascorbic acid, resorcinol, and oxalate can be determined based on the inhibition of Mn(II)-catalyzed oxidation of malachite green with KIO<sub>4</sub>, formaldehyde-catalyzed oxidation of neutral red by bromate, and tungsten-catalyzed oxidation of the iodide ion by H<sub>2</sub>O<sub>2</sub>. Organic compounds such as acetaminophen (paracetamol), phenol, and nitroprusside, have also been determined by an inhibition effect on the photolysis of a methyl viologen/EDTA/acridine yellow system that was irradiated with a halogen lamp and by measuring the time required for reaching a preset absorbance.

**Enzymatic reactions:** UV–visible absorption spectrophotometric determination of enzyme inhibitors is much more popular than that of enzyme activators. Drugs such as neostigmyne, chlorpromazine, and cisplatin can be determined by inhibition of soluble or bound enzymes, viz., acetylcholine sterase, Nicotinamide adenine dinucleotide hydrogenase (NADH), and peroxidase, respectively.

*Genomic, proteomic, and phenomic analyses:*

The genome is the total sum of all the genes in an organism. Normally, every cell in an organism contains an identical copy of the genome. During the past decade, an estimated 180 microbial genome sequencing projects churned out ~86 microbial genomes that have been sequenced completely and published. In molecular microarray fabrication, nanoliter sized volumes are arrayed instantaneously so that simultaneous characterization of genes and bacteria can be achieved in a very short time. Attention is now turning to the study of proteins as harvesting of knowledge from genome sequence data requires systematic and large-scale study of proteins. The ensemble of proteins related to a genome is known as a proteome. The understanding of proteomes is more useful than that of a genome; (1) as every cell in an organism contains an identical genome but proteins use the different genetic information to form different types of cell – liver, muscle, bone, or blood cells; (2) for selecting 20 or so genes out of 160 000; (3) because many human diseases are related to incorrect modification of normal proteins and thus allow diagnosis of the disease; and (4) because proteins are targets for nearly all drugs used for treatment. Proteomic analysis covers large-scale analysis of protein structures, protein expression, and protein interactions. Little research has been done on describing bacterial phenotypes in a more comprehensive manner, even though tremendous advances in DNA microarray and proteomic methodologies have been made. The advantage of phenomic research is the ability to conduct simultaneous testing of numerous bacterial phenotypes using an automated instrument by measuring the absorbance of a substrate color change of a tetrazolium indicator.

*Online analysis:* Online sample processing techniques such as flow injection provide advantages such as reliability, sample economy, ease of automation, measurement standardization, high speed, optional sample dilution, and the ability to derivatize the analyte so as to suit the analyzer/detector. These procedures facilitate the online monitoring of fermentation substrate materials, respiratory gases, and biomass. The modifications to flow injection analysis for accurate discontinuous flow operation include sequential injection analysis and bead injection spectroscopy. The most recent invention in online techniques is the introduction of the Lab-on-a-Valve, which opens the way to development of a novel type of microflow analytical system monitored by UV–visible spectrophotometry using fiber optics. This system is an ideal tool for fermentation monitoring.

## Sample Processing via Preconcentration/Enrichment

Typically, when measurements are made at the trace and ultratrace levels, the sample volumes are relatively large. Hence, direct determination of traces of organics using spectrophotometry is still difficult because of the insufficient sensitivity and selectivity of the methods used. Therefore, pretreatment of samples, such as preconcentration of the analyte before its determination, is frequently necessary. Preconcentration improves the analytical detection limit, increases the sensitivity by several orders of magnitude, enhances the accuracy of the results, and facilitates calibration. The preconcentration approaches that can be employed prior to spectrophotometric determination of traces of organics are summarized below.

### Liquid–Liquid Extraction

Liquid–liquid extraction (LLE), although used primarily as a separation technique, is an important enrichment technique. LLE is based on the distribution of an analyte between two essentially immiscible solvents. The distribution ratio of an analyte is defined as the ratio of its total concentration in the organic phase to that in the aqueous phase at equilibrium. When the desired organic compound is extracted, the larger the distribution ratio of the analyte and the smaller that of the matrix, the higher the recovery of the organic compound and enrichment factor. When the matrix is removed by extraction, the reverse is required for successful enrichment. After the extraction, back washing of matrix components selectively from the organic phase into the aqueous phase improves the enrichment factor.

### Supercritical Fluid Extraction

The term ‘supercritical’ denotes conditions above a critical temperature and pressure. However, interesting behavior occurs throughout the critical region. The advantages of supercritical fluid extraction (SFE) over conventional extraction methods include more rapid extraction rates, the possibility of more efficient extractions, increased selectivity, possible analyte fractionation during extraction, and high-enrichment factors and compatibility with online analysis methods. Offline SFE, ultrasonic SFE, and online SFE methodologies find widespread application for preconcentration of organics present in complex matrices. Extraction rates generally increase over an order of magnitude compared with conventional Soxhlet extraction methods. On the other hand, online SFE methods combine sample

preparation and analysis and provide the potential for rapid and highly sensitive analyses.

### Gel and Ultrafiltration

Gel filtration is based on the inclusion and subsequent elution for fractionating and enriching dissolved organic compounds according to their molecular size or molecular weight differences by passing through a porous polymeric gel such as a molecular sieve.

Ultrafiltration is employed to enrich organic compounds with appropriate cut-off molecular weights using a variety of ultrafiltration membranes.

### Dialysis

In an *in situ* dialysis technique, a dialysis bag filled with pure solvent is directly immersed into a natural aqueous sample *in situ* to enrich truly dissolved forms of organic compounds without substantial influence of adsorption on the walls of vessels and apparatus.

### Solid-Phase Extraction

Solid-phase extraction (SPE) has emerged as a powerful tool for separation/enrichment of organics. The basic principle of SPE is transfer of analytes from a liquid phase to active sites of an adjacent solid phase or sorbent. The sorbent material retains selectively the analyte, which is subsequently stripped by an appropriate solvent. Sorbents include activated carbon, silica and silica gel, glass beads, cellulose, polyurethane foam, and polymer supports such as macroreticular XAD resins, etc. The advantages of SPE over LLE include higher enrichment factors, absence of emulsion, safety with respect to hazardous samples, minimal costs due to low consumption of reagents, flexibility, ease of automation, and, more importantly, greater environmental friendliness as minute volumes of solvents and reagents are used.

### Molecular Imprinted Polymers for SPE (MIP-SPE)

Molecular imprinting is a way of making artificial locks for molecular keys. The selected molecule (target analyte) is first mixed with a variety of lock-building blocks (functional monomers). The building blocks and the key are allowed to bind each other strongly or loosely (Figure 3a). The so formed complexes consisting of building blocks and keys are glued together in order to fix the building block positioned around the key by polymerization (Figure 3b). Finally, by removing the molecular key, it leaves a construction that is selective for the original key and will not recognize any other key (Figure 3c).

**Figure 3** Schematic representation of molecular imprinting process: T, template; A, mixing and prearrangement; B, polymerization; C, template washing and Soxhlet extraction. (Reproduced with permission from Rao et al. (2004) *Trends in Analytical Chemistry* 23: 24.)

Thus, the molecular memory introduced into the polymer is now capable of enriching the analyte with high specificity. One of the many attractive features of the molecular imprinting method is that it can be applied to a diverse range of analytes. The imprinting of the organic molecules, viz., amino acids, peptides, pesticides, pharmaceuticals, nucleotide bases, steroids, and sugars is now well established. The importance of polymer- and template-related factors in the development of MIPs for use in SPE preconcentration of organics has been well brought out recently in the area of biopharmaceutical and environmental analyses. In addition, preparation of MIP-SPE materials is simple and convenient.

### Hyphenated Techniques

Hyphenation refers to the online combination of a separation technique and a spectroscopic detection method that provides structural information on the analytes concerned. Liquid chromatography (LC), mass spectrometry (MS), and gas chromatography (GC) are the most popular hyphenated techniques in use today. The choice of detection is important to the overall scheme of LC make up and is contingent upon criteria such as the noise, sensitivity, and linearity. Of the two basic categories of detectors, viz., solute and bulk property detectors, UV detection belongs to the former category.

### Hypernation and Extended-Hypernation Techniques

The real problem, as of now, is not how to improve the analytical performance but how to handle the plethora of data generated per run. Thus, a combination different hyphenated techniques is an obvious

choice for tackling challenging analytical problems and is usually called a hypernation – a term indicating that one is now ‘one higher than’ (or hyper) hyphenation. On the other hand, the obvious disadvantage of such hypernation is that, whilst it may be efficient in terms of run time, sample size, and data correlation, it is very inefficient in utilization of expensive spectrometers. Recent developments indicate the introduction of an extended hypernation technique that combines UV, MS, Inductively coupled plasma-MS (ICP-MS), nuclear magnetic resonance, Fourier transform infrared, etc. detectors for LC-based operations. However, the whole area of LC-based (extended) hypernation is still in an early stage of development, and major improvements can be expected. As the analytical problems that have to be solved tend to become increasingly complex, there is every reason to believe that in the longer term the benefits will certainly outweigh the costs – not for routine problem solving but for whatever is new, challenging, and complicated.

### Detectors in UV-visible Spectroscopy

Advances in detectors have been important for techniques like UV-Visible spectrophotometry and high-performance LC (HPLC)-UV, where rapid progress has been made over the recent past. Photomultiplier tubes continue to enjoy high popularity in forward optic instruments. However, in the past decade, detectors that permit simultaneous acquisition of spectral information over the whole wavelength range have dominated the market. Simultaneous detection may be achieved using a single detector that receives encoded information, which is later decoded mathematically (such as by Fourier transformation) or using multichannel techniques in which spectral information is either spatially or temporally dispersed (optical imagers). The rapid development of the later devices took place due to advances in semiconductor technology and proliferation of powerful and relatively inexpensive microprocessor systems. Thus, photodiode detector arrays (PDAs), despite their relatively high price, have been widely used as multichannel detectors for simultaneous monitoring at all wavelengths, in addition to detection of transient signals in HPLC and flow injection analysis. Thus, a complete spectrum can be recorded within a few milliseconds because the scan time is not affected by the movement of the diffractor. It is not exaggerating to say PDA detection in conjunction with LC will soon be the most frequently used technique for analysis of organic compounds that cannot be analyzed using GC.

### Chemometric Approaches in UV-visible Spectroscopy

Chemometrics is the science of relating measurements made on a chemical system (including dynamic chemical processes) to the state of the system via application of mathematical or statistical algorithms. It is clear from this definition that chemometrics is data based. The goal of many chemometric techniques is the production of an empirical model, derived from data, that allows one to estimate one or more properties of a system from measurements. The four important performance attributes that can be improved through the use of chemometric techniques are accuracy, precision, robustness, and reproducibility.

As in other analytical techniques, a natural trend in UV-visible spectrophotometry is an approach to multicomponent analysis. The quantitation of compounds with highly overlapping spectra in a mixture has always been a difficult analytical problem, especially at unequal analyte concentration levels. With the advent of the fast scanning PDAs mentioned above and low cost computers capable of processing complex data sets, new horizons have been opened for mathematic processing of the information acquired. Two powerful signal processing techniques, viz., multiwavelength and derivative spectrophotometry, have been developed rapidly in the recent past.

### Multiwavelength Simultaneous Analysis

The advent of low priced powerful microcomputers has enabled easy processing of spectrophotometric data. In addition, fast scanning detectors have allowed elimination of errors resulting from poor time stability when a dual wavelength method is used with a single wavelength spectrophotometer. Modern multiwavelength analysis utilizes the reversed matrix representation of Beer-Lambert's law. This can be combined with chemometric techniques such as principal component analysis (PCA) and partial least squares (PLS).

### Principal Component Analysis

The purpose of PCA is to give an overview of the dominant information patterns in the data. These are the relationships between the spectra and the wavelengths which can be explored mathematically or graphically. PCA sets out to express the main information of a calibration set of spectra in terms of a lower number of variables – these are the principal components of the original data matrix. This has the effect of maximizing the amount of information in a

greatly reduced number of variables and allows a much more efficient understanding and manipulation of the data. It is achieved by performing an eigen analysis of the covariance matrix of the spectral data matrix. One of the most important aspects of PCA is to choose how many of the components are significant for modeling the original data. The significance is of both a statistical and chemical nature. In essence, the information content of a large spectral dataset is distilled into a small number of principal components.

For quantitative analysis applications, these principal components can then be regressed with calibration values of the standards to produce the system model. This model is then used to predict the assay values of a test sample from its spectrum. Together with the assay figures, these models can indicate the errors associated with the prediction and validity of applying the model against the test sample. These are important diagnostics when the approach is a part of an automated analysis system and must be made to failsafe on the assay.

### Partial Least Squares

PLS is being used as a data reduction/modeling technique for spectral data. PLS is similar to PCA in extracting a series of principal components from the data but differs in that both the spectral data and the property or assay data are used together in an iterative fashion to build a model. The chemical data are used to find a pattern in the spectroscopic data that correlates with them. This ensures that the estimated regression factors have relevance toward the chemical values.

The advantage of PLS over PCA is to model a system with both fewer and more relevant dimensions than PCA. Hence, the model in PLS more robust and easier to be visualized by the user.

### Derivative UV-visible Spectrometry

The rapid evolution of microcomputers has led to the derivative transformation of spectral data, which offer a powerful tool for both qualitative and quantitative analysis of mixtures of organic compounds. The method has found increasing application in UV-visible spectrophotometric analysis of organics for background correction and for resolution enhancement. The ability to eliminate matrix interferences such as irrelevant absorption and light scattering has been of particular value.

It is clear that the second derivative of radiation intensity becomes nonlinear with concentration, except where the term  $(d\epsilon/d\lambda)$  is zero. It is common and convenient to measure absorbance,  $a(\log \phi_0/\phi)$ , at a defined wavelength,  $\lambda$ .

$$a = \epsilon bc$$

Thus

$$d^n a = d\lambda^n = d^n \epsilon / d\lambda^n bc$$

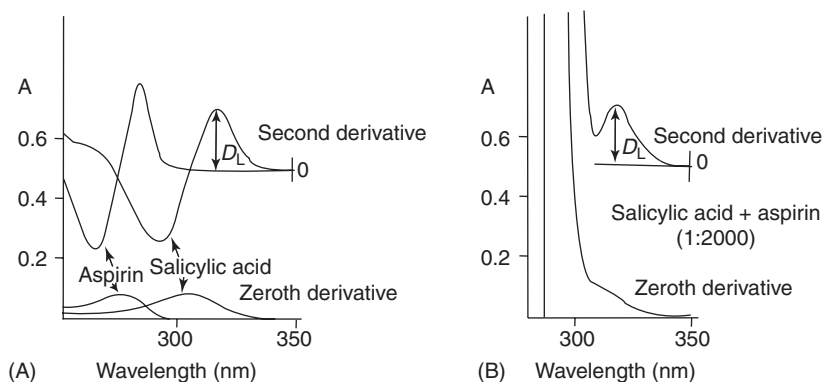

where  $n$  is the derivative order. When the matrix interference can be approximated as a linear function, the first derivative yields a function where the interference is reduced to a constant:

$$Y = ax + K$$

$$\frac{dy}{dx} = a$$

$$dy/dx = a$$

For total elimination of the matrix interference from the spectrum of interest, the derivative of order  $n + 1$  is therefore needed, where  $n$  is the highest power of the polynomial equation that represents the matrix. Matrix absorption can often be approximated by a linear function, so that the second derivative transformation can be used to eliminate

**Figure 4** Use of derivative spectra to determine salicylic acid in aspirin (A) the zeroth and second derivatives of both materials are shown. (B) The equivalent spectra of the mixture in a 1:2000 ratio are shown. (Reprinted with permission from Kitamura K and Majima R (1983) *Analytical Chemistry* 55: 54. © American Chemical Society.)

such interferences completely. An example of application of second derivative measurements is illustrated in **Figure 4**. In determination of salicylic acid in aspirin powder, the salicylic acid signal is obscured by the overwhelming concentration of acetyl salicylic acid. However, the second derivative spectrum yields a distinct peak for the salicylic acid, which can be used for the determination with good precision. In many situations, however, interferences can be attributed to the presence of other UV absorbing substances. Depending on the relative positions of the particular analytical bands concerned, polynomial equations of various degrees will be required in order to describe the interfering component effectively. Interference in such samples can often be described by a quadratic function requiring a third order derivative for complete deconvolution of overlapping UV–visible spectra.

### Introduction

Ultraviolet (UV)–visible spectrophotometry is widely used in biochemistry, both for the determination of species and for studying biochemical processes. This technique enables the determination of micromolar concentrations of substances and has a broad scope of application in this field since most biochemical compounds absorb in the UV–visible region or can be converted into some absorbing derivative. On the other hand, this often results in interferences during the determination of the compound of interest, interferences that are minimized by using either derivative spectrophotometry, particularly in the presence of strong background absorption or, to a lesser extent, differential spectrophotometry.

Spectrophotometric methods are usually less sensitive than fluorimetric ones, which accommodate concentrations of a few nanomoles per milliliter; however, their range of applications are much broader,

including inorganic species, organic compounds, proteins, etc., since UV–visible absorption is more universal a property than fluorescence. Spectrophotometry is especially useful for monitoring enzymatic reactions, either to determine the reaction products directly or to measure the reaction rate.

The most salient applications of UV–visible spectrophotometry to biological systems classified according to the type of substance studied are described herein.

### Inorganic Ions

Inorganic ions in biological systems can be quantified by spectrophotometric methods provided they are present at suitable concentrations (of a few micrograms per milliliter or higher) and other species in the medium exhibit little or no absorption. However, many elements including aluminum, cadmium, chromium, and nickel usually cannot be determined by UV–visible spectrophotometry, because they occur at very low concentrations in biological systems.

UV–visible spectrophotometric determinations of inorganic ions require the use of a reagent forming a

**Table 1** Characteristics of inorganic species by UV–visible spectrophotometric determinations

Inorganic species	Reagent	$\lambda_{\max}$ (nm)
Fe	1,10-Phenanthroline	510
	Bathophenanthroline	
Mo	Dithiol	680
Cu	Cuproine	546
	Neocuproine	
Mg	Thiazol yellow	540
Nitrate (reduction to nitrite)	Griess	540
Sulfide	<i>N-N</i> -Dimethyl- <i>p</i> -phenylenediamine	669
Ca	Sodium cloranalate	520

colored compound with the species to be determined. The compound can be a complex, an absorbing product (a lacquer), or an oxidized or reduced product, and should be stable under the experimental measurement conditions.

Ammonium ion is one of the inorganic species most frequently determined by UV–visible spectrophotometry. It is freed by the Kjeldahl method from organic matter and can be spectrophotometrically determined by reaction with phenol and hypochlorite in the presence of nitroprusside ion, with which it yields a blue compound (indophenol) with an absorbance maximum at 625 nm. Another alternative, especially avoiding the use of phenol, is by measuring the absorbance at 660 nm of an indophenol blue derivative generated by the reaction of ammonium ion with sodium salicylate in the presence of hypochlorite ion. These procedures are routinely used for the determination of ammonium ion with autoanalyzers.

Phosphate is another inorganic species commonly encountered in biological systems that can be assayed spectrophotometrically. It reacts with ammonium molybdate to form 12-molybdophosphate heteropolyacid  $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ , which is reduced by ascorbic acid to a blue product ( $\lambda_{\max} = 820 \text{ nm}$ ).

Other common UV–visible spectrophotometric determinations of inorganic species are listed in **Table 1**.

Kinetic catalytic methods make use of a number of inorganic oxidation indicator reactions, the most representative of which is probably the decomposition of hydrogen peroxide with different reagents catalyzed by copper, iron, manganese, etc., which allows these species to be determined by UV–visible spectrophotometry.

## Common Organic Compounds

Some organic compounds commonly occurring in biological systems absorb sufficiently in the UV–visible region, whereas others show little or no

**Figure 1** Absorbance spectra of chlorophylls *a* and *b* dissolved in 80% acetone. (Reproduced with permission from Pineda M and Cárdenas J (1988) *UV–Visible Spectrophotometry of Biological Compounds (Espectroscopía Ultravioleta–Visible de Compuestos Biológicos)*. Córdoba (Spain): Publications of Monte de Piedad and Caja de Ahorros of Córdoba.)

absorption so that they require some transformation into a colored, absorbing substance.

Chlorophylls are among the organic compounds whose intrinsic absorption is adequate for spectrophotometric quantification. These substances, responsible for the green color of plants, are insoluble in water but soluble in organic solvents (ether, acetone). The absorbance spectrum varies between chlorophylls (**Figure 1**) as a result of the presence of different substituents in the parent protoporphyrin–magnesium structure. Chlorophyll in plants is determined by grinding fresh vegetable material and extracting the pigment into an organic solvent.

However, organic biological compounds must be converted into colored species for their determination. This can be accomplished by means of a redox reaction such as that which takes place between reducing sugars (aldoses and ketoses) and ammonium molybdate (which yields molybdenum blue,  $\lambda_{\max} = 700 \text{ nm}$ ), picric acid (which is reduced to picramic acid,  $\lambda_{\max} = 460 \text{ nm}$ ), or uric acid (which reduces phosphomolybdate heteropolyacid). Reducing sugars can also be determined by reduction of hexacyanoferrate(III) to (II) and subsequent formation of Prussian blue (the Park and Johnson method). Other conversion reactions involve the formation of condensation products such as those of ketoses with diphenylamine or glyoxylic acid (resulting from the hydrolysis of allantoic acid, which in turn originates from hydrolysis of allantoin) with 2,4-dinitrophenylhydrazine. The converted products can also be of a different nature (e.g., a red salt obtained by reaction of creatinine and picric acid, the unknown

substance produced by glutathione and alloxan, and the red product yielded by fructosamine on reduction of nitroblue tetrazolium salts).

Unsaturated lipids in blood serum can be spectrophotometrically determined by using sulfuric acid and vanillin phosphate, which produces a red substance of unknown composition whose absorbance is measured at 520–530 nm.

## Amino Acids

Amino acids can easily be determined in a direct manner since they absorb significantly in the near-UV region. The main problem in their quantitation in biological systems is the strong interferences from other species present. Interferences can largely be overcome by using derivative spectrophotometry, which minimizes matrix effects. For example, phenylalanine and tryptophan can be determined using their second-derivative spectra; phenylalanine at 250–265 nm and tryptophan at 290–295 nm.

A similar procedure based on second- and fourth-derivative spectra can be used for the resolution of mixtures of phenylalanine, tryptophan, and tyrosine. Fourth-derivative spectra show strong bands for tyrosine and phenylalanine that are markedly affected by the polarity of the medium. Other amino acids have been determined in various biological samples, especially protein hydrolysates, with varying results.

Derivatization reactions are also commonplace in the determination of amino acids. One such reaction is that with ninhydrin-ascorbate. In the presence of amino acids, ninhydrin (triketohydrindane hydrate) is reduced to hydridantin by ascorbic acid while the amino acids undergo oxidative deamination with the formation of ammonium ion, which is condensed with hydridantin to yield a colored product with maximal absorbance at 405 and 575 nm. The procedure is often used for the determination of amino acids in protein hydrolysates.

Another interesting subject is the use of a reagent that allows the stoichiometry and reactivity of amino acid side chains to be monitored spectrophotometrically. For example, the classical reagent 5,5'-diethiobis-(2-nitrobenzoic acid) (known as Ellmans reagent) is very selective for the thiol side chain of cysteine residues. Others reagents used for this general purpose are: (1) trinitrobenzenesulfonic acids, which react well with the amine groups of reactive lysine residues, (2) tetranitromethane for modification of tyrosine side chains to give a colored product that is easily monitored by spectrophotometry, (3) diethylpyrocarbonate for histidine residues, (4) 2-nitrophenyl-sulphenyl chloride, which reacts with

tryptophan side chains to give products that can be measured spectrophotometrically.

## Proteins

Quantitative determination of proteins is often needed to determine their concentrations and changes in cell growth and differentiation processes or in enzyme purification procedures.

Occasionally, a peptide can be quantified directly provided it exhibits a significant, characteristic absorbance. Otherwise, a derivatizing reagent must be employed to obtain an adequate absorbance in the UV–visible region. Examples of these two types of application are detailed below.

### Direct Absorbance Measurements

Most proteins absorb strongly in the near-UV and visible regions. The polypeptide portion of the protein usually absorbs at short wavelengths; its absorbance, mainly due peptide bonds, appears as a weak band ( $\lambda_{\max} = 215$  nm,  $\epsilon = 100 \text{ l mol}^{-1} \text{ cm}^{-1}$ ) because of an  $n \rightarrow \pi^*$  transition and a strong band ( $\lambda_{\max} = 190$  nm,  $\epsilon = 7000 \text{ l mol}^{-1} \text{ cm}^{-1}$ ) produced by a  $\pi \rightarrow \pi^*$  transition. A number of other amino acids including tryptophan ( $\lambda_{\max} = 219$  nm) absorb in the same zone. Table 2 lists the characteristic absorbance parameters of some selected proteins.

The prosthetic groups responsible for the absorbance of many proteins at long wavelengths can be of very different nature. The principal compounds in this respect are flavins, tetrapyrroles, carotenoids, and flavonoids.

Flavins are riboflavin derivatives and includes a group of chromophoric substances that exhibit absorbance bands in the visible region (usually between

**Table 2** Absorbance parameters for selected proteins

Protein	Source	$\lambda$ (nm)	$\epsilon$ ( $\text{l mol}^{-1} \text{ cm}^{-1}$ )

445 and 460 nm). They act as prosthetic groups in flavoproteins and flavoenzymes. Tetrapyrroles and their derivatives (porphyrins, haemes, chlorophylls, and bile pigments), all of which play major biological roles, absorb strongly in the near-UV and visible regions. Porphyrins absorb very strongly in the region from 450 to 650 nm. Their bands are highly sensitive to environmental factors and to metal ions and ligands; thus, the visible spectra of oxyhaemoglobin, deoxyhaemoglobin, and carboxyhaemoglobin are rather different from one another, which allows their selective quantification. The state of oxidation of iron in ferredoxin also influences its absorption. The spectra of the bile pigments bilirubin ( $\lambda_{\max} = 425$  nm) and biliverdin ( $\lambda_{\text{em}} = 378$  and 680 nm) are also rather different. On the other hand, carotenoids (terpenoids consisting of eight isoprene units with several conjugate bonds) can be of two types, xanthophylls and carotenes, which give absorbance bands in the 400–550 nm region.

The absorbance spectra of proteins are not the sum of those of its constituent amino acids and prosthetic groups, since the protein structure may undergo a number of interactions (hydrogen bonding, ionic interactions between charged or polarized groups) that prevent a detailed analysis of protein structure from UV–visible spectra alone. The problem is further complicated by the influence of the solvent used. All these factors diminish the qualitative value of the spectra. However, direct protein absorbance is very often used for quantitative purposes. Only if the absorbance is very weak or nonspecific does the protein need to be derivatized for quantification.

The most frequently used procedure for direct quantification of proteins is that of Warburg and Christian. It is based on the fact that tryptophan and tyrosine absorb UV radiation maximally at 280 nm and occur at fairly constant concentrations in proteins. Accordingly, the protein concentration of a solution can be determined by measuring its absorbance at 280 nm ( $A_{280}$ ). However, this procedure requires further corrections since nucleic acids and their nitrogen bases, either in free form or as nucleotides, also absorb in the measuring region ( $\lambda_{\max} = 260$  nm). This compels one to determine experimentally the  $A_{280}/A_{260}$  ratio for several samples containing different proportions of nucleic acid in order to calculate a correction factor that is multiplied by  $A_{280}$  to obtain the protein concentration.

### Derivatization

There are three prime methods for quantification of proteins based on derivatization reactions: the biuret, Lowry, and Bradford methods.

The biuret method is based on the fact that proteins (and, as a rule, all substances containing two or more peptidic bonds) react with copper to form a colored complex whose absorption ( $\lambda_{\max} = 454$  nm), in the presence of excess copper, is proportional to the amount of protein present. The reagent is obtained by dissolving 1–5 g of copper(II) sulfate and 6 g of sodium potassium tartrate tetrahydrate in 3% sodium hydroxide. Bovine serum albumin is used as standard. The most serious drawback of this method is its poor sensitivity.

The Lowry method, more sensitive than the biuret method, affords the determination of protein at the microgram per milliliter level. The procedure involves two reactions: that of the protein with alkaline copper solution (the biuret reaction) and reduction of the Folin–Ciocalteu reagent by tyrosine and tryptophan residues of the protein. The Folin–Ciocalteu reagent is prepared by boiling a solution containing sodium tungstate, sodium molybdate, and phosphoric and hydrochloric acids, which produces molybdophosphate and tungstophosphate ions. The absorbance is measured at 750 nm. The Lowry method has also been applied to proteins in whole cells. Like the biuret method, it is subject to some limitations and interferences (particularly those from ammonium salts, glycine, and mercaptans). In addition, variations in the tyrosine and tryptophan contents from protein may introduce some uncertainty in the determinations, so the method is more practical for determining concentration changes than absolute protein concentrations. The Lowry method has also been applied by exploiting solid-phase spectrophotometric techniques.

The Bradford method is based on the absorbance of Coomassie Brilliant Blue on the protein to be determined, which results in a spectrum shift of the dye from 465 to 595 nm. The absorbance at 595 nm is proportional to the protein concentration. Bovine serum albumin is used as standard. The reaction is susceptible to interferences from surfactants and alkalinity of the solution. The main advantage of the method is rapidity, which enables efficient application to many samples.

A micromethod has been developed using the Bradford method for studying the proteins present in cell membranes.

Proteins can also be determined by 1% bicinchoninic acid solution in alkaline medium, to produce a red compound. The absorbance is measured at 562 nm against a reagent blank. Proteins can be determined in the interval  $0.5\text{--}10\ \mu\text{g ml}^{-1}$ . The method offers a one-step alternative to the methods of Lowry and Bradford and is less subject to interferences.

In recent years, diverse chelating agents have been introduced for proteins quantification: Arsenazo III, fuchsin acid, methyl blue, bromophenol blue, methylene blue, etc.

Another common determination is that of haemoglobin, a major component of red blood cells. The method involves oxidation of haemoglobin with hexacyanoferrate(III) to form methaemoglobin, and further reaction with cyanide ion to form cyanmethaemoglobin that presents maximal absorptivity at 540 nm ( $\epsilon = 4.4 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$ ). The procedure is carried out by using Drabkin's reagent, a solution containing potassium hexacyanoferrate(III), potassium cyanide, sodium phosphate, and a surfactant (e.g., Triton X-100). The method can also be applied to whole blood samples.

Haemoglobin can also be determined after complex formation with inositol hexaphosphate that is quantified by differential spectrometry to avoid the strong absorbance of the protein.

## Nucleic Acids

Nucleic acids absorb strongly in the near-UV region because of the purine and pyrimidine bases they contain. However, the energies of the strong transitions for the five most common bases are virtually the same, which results in very close absorbance maxima (260, 246, 259, 265, and 267 nm for adenine, guanine, uracil, thymine and cytosine, respectively), even though their exact position is pH dependent. This makes it rather difficult to assess the contribution of each band to the spectra of DNA or RNA, which exhibit a broad absorbance band between 240 and 280 nm due to the bases. The spectrophotometric quantification of nucleic acids is also hindered by marked variations in the spectra with pH as a result of the ionization of their constituent bases.

Interactions between nucleic acids and proteins are also hard to elucidate because of the difficulty involved in determining the individual contribution of each substance: protein bands are usually masked by the strong absorbance bands of nucleic acids.

Nucleic acids can also be quantified by derivatization. Thus, RNA is subjected to a multistep procedure in which the nucleic acids are decomposed to pentoses, which are subsequently converted into furfural by heating in an acidic medium. The furfural in turn reacts with orcinol to form a bluish-green condensation product with  $\lambda_{\text{max}} = 660 \text{ nm}$ . The deoxyribose of DNA is quantified with diphenylamine in an acid medium. The linear determination range is from 10 to 100  $\mu\text{g ml}^{-1}$  and the procedure is free from the interference of RNA.

## Study of DNA Stability

Knowledge of the thermodynamics of DNA hybridization and secondary structure formation is necessary for understanding DNA replication fidelity, mismatch repair efficiency, and the mechanism of DNA triplet repeat diseases. In addition, RNA folding thermodynamics is an important aspect to understand ribozyme catalysis, as well as the regulation of protein expression, mRNA stability, and the mechanism of proteins synthesis by the ribosome. With the genome sequencing era upon us, to predict the folding and hybridization thermodynamics of DNA and RNA will be important, so that accurate diagnostics tests for genetic and infectious diseases can be developed.

For example, the temperature-induced transition between native and random coil states of a nucleic acid can be conveniently monitored by UV spectrophotometry. The reason for this is that stacked bases have a lower absorbance per base than unstacked bases; this is called hypochromicity, which is defined as:

$$\% \text{hypochromicity} = 100 \frac{A_{\text{denatured}} - A_{\text{native}}}{A_{\text{native}}}$$

where  $A_{\text{denatured}}$  and  $A_{\text{native}}$  are the absorbances at high and low temperatures, respectively. The absorbance versus temperature profile is commonly referred to as a UV absorbance melting curve (Figure 2). As the temperature increases, the ratio of molecules in the single stranded versus native states increases, resulting in an increase in the UV absorbance. The melting temperature,  $T_M$ , is defined as the temperature at which half of the strands are in the native state and half are in the 'random coil' state. Whereas many methods such as circular dichroism and nuclear magnetic resonance can be used to monitor

**Figure 2** Typical experiment UV melting profile. At a given temperature, the fraction of strands in the duplex state,  $\alpha$ , is given by the ratio  $a/(a+b)$ , where  $a$  and  $b$  are the respective vertical distances from the upper and lower baselines to the experimental melting curve. (Reproduced with permission from Gore MA (ed.) (2000) *Spectrophotometry and Spectrofluorimetry: A Practical approach*, p. 330. Oxford: Oxford University Press.)

thermal denaturation, UV absorbance is the most sensitive due to the high molar absorptivity of the bases.

## Enzymatic Analysis

Enzyme analyses are common in clinical and biochemical laboratories, which exploit mostly UV-visible spectrophotometry for this purpose. Basically, the concentration of a substance that takes part in an generic enzymatic reaction  $A \rightarrow B$  can be determined in two ways: (1) by direct determination of the concentration of the reaction product (B) after the reaction is completed; and (2) by measuring the rate of the reaction, which must be related to the concentration of the studied substance (substrate) or the cofactor, activator, or inhibitor. In the former procedure, the reaction should be very fast, whereas the opposite holds true in the latter. In both cases, spectra of the reactant (A) and product (B) should be different. Experimentally, the procedure involves measuring the decrease in the absorbance of A or the increase in that of B. For example, the direct determination of uric acid ( $\lambda_{\text{max}} = 292 \text{ nm}$ ,  $\varepsilon = 1.2 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$ ) with uricase requires the quantifications of absorbance lessening at 292 nm. In the determination of nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ) with alcohol dehydrogenase, where  $\text{NAD}^+$  is reduced to NADH ( $\lambda_{\text{max}} = 340 \text{ nm}$ ,  $\varepsilon = 6.22 \times 10^3 \text{ l mol}^{-1} \text{ cm}^{-1}$ ), the increase in the absorbance is monitored at 340 nm. If A or B lacks a characteristic spectrum, then one must use coupled reactions in which B acts as substrate for a second enzymatic reaction (indicator reaction) whereby B is quantified. Thus, glucose can be oxidized to gluconic acid by glucose oxidase and the released hydrogen peroxide can be used to oxidize *o*-dianisidine in the presence of peroxidase to obtain a colored product to be spectrophotometrically measured.

Several enzymatic methods use the coenzyme nicotinamide adenine dinucleotide in its oxidized ( $\text{NAD}^+$ ) and reduced (NADH) forms, which makes a very useful reversible system as they are involved in several enzymatic reactions and have rather different absorption spectra (Figure 3). For example, glucose in blood serum can be determined with glucose dehydrogenase according to reaction [I] by monitoring the absorbance increase of NADH at 340 nm:

Lactate dehydrogenase (LDH) in serum can be measured by its catalytic action on the reaction

**Figure 3** Absorbance spectra of the coenzyme nicotinamide adenine dinucleotide in its oxidized ( $\text{NAD}^+$ ) and reduced (NADH) forms. (Reproduced with permission from Pineda M and Cárdenas J (1998) *UV-Visible Spectrophotometry of Biological Compounds (Espectroscopía Ultravioleta-Visible de Compuestos Biológicos)*. Córdoba (Spain): Publications of Monte de Piedad and Caja de Ahorros of Córdoba.)

between pyruvic acid and NADH (eqn [II]), which is also monitored by absorption decrease of NADH at 340 nm:

Nicotinamide adenine dinucleotide phosphate, which occurs in oxidized ( $\text{NADP}^+$ ) and reduced (NADPH) forms with markedly different absorption spectra and an absorptivity similar to  $\text{NAD}^+$  can also be used for enzymatic analysis. Thus,  $\text{Mg}^{2+}$  in serum can be measured by the oxidation reaction of isocitrate with  $\text{NADP}^+$ , catalyzed by isocitrate dehydrogenase (IDH) (eqn [III]):

If a fixed concentration of IDH and saturating amounts of isocitrate and  $\text{NADP}^+$  are used, the rate of the enzymatic reaction is proportional to the concentration of magnesium over the range from  $1.0 \times 10^{-6}$  to  $2.0 \times 10^{-4} \text{ mol l}^{-1}$ .

Spectrophotometric methods can be applied to both dissolved and immobilized enzymes. Immobilized enzyme columns are increasingly being used in flow injection analysis as a means of increasing the sample throughput.

## Other Aspects

In the recent past, a certain number of issues related to redox processes in biological systems and the

effect of free radicals have been widely studied. For example, reactive oxygen species (ROS) are produced during normal cellular function. ROS include hydroxyl radicals, superoxide anion, hydrogen peroxide, and nitric oxide. They are very transient species due to their high chemical reactivity that leads to lipid peroxidation and oxidation of DNA and proteins. Under normal conditions, antioxidant systems of the cell minimize the perturbations caused by ROS. When ROS generation is increased to an extent that overcomes the cellular antioxidants, the result is oxidative stress. It is now clear that several biological molecules, which are involved in cell signaling and gene regulation systems, are very sensitive to the redox state of the cell. On the other hand, antioxidants are substances that delay or prevent the oxidation of cellular oxidizable substrates. The prevention of the oxidation is an essential process in all aerobic organisms, as decreased antioxidant protection may lead to cytotoxicity, mutagenicity, and/or carcinogenicity.

In general, the determination of the redox processes and the evaluation of antioxidant capacity can be achieved by electrochemical techniques, such as cyclic voltammetry. On the other hand, as free radicals are very reactive they are usually analyzed by measurements of secondary products ( $\text{H}_2\text{O}_2$ , oxidized proteins, etc.) by fluorimetry in combination with fluorescent dyes, such as dichlorofluorescein. This procedure offers more advantages than the classical spectrophotometric determination based on the oxidation of *o*-dianisidine, due to which the sensitivity of this last procedure is limited to  $\sim 200 \text{ nmol l}^{-1} \text{ H}_2\text{O}_2$  under ideal conditions.

Diverse UV-visible spectrophotometric procedures have been described for the measurement of enzymatic activities in several diseases related to oxidative stress. Thus, catalase activity has been evaluated by measurement of  $\text{H}_2\text{O}_2$ , and glutathione peroxidase (GSPHx) was quantified by continuous photometric monitoring of oxidized glutathione; the conversion of NADPH to NADP was evaluated using UV absorbance at 340 nm. GSPHx activity was calculated after subtraction of the blank value as micromole of NADPH oxidized per minute per milligram protein (International unit per milligram protein) or micromole of NADPH oxidized per minute per gram Hb (International unit per gram Hb).

Flow techniques have been proposed as an alternative to conventional procedures. For example, due to the short lifetime of superoxide in aqueous solution, it still has been possible to adapt the useful and

versatile methods of stopped flow spectrophotometry to measure catalysis by superoxide dismutases. The method rapidly mixes superoxide into aqueous solutions containing the enzymes and follows the subsequent decay of superoxide by detecting its UV absorbance to 250 nm.

### Introduction

Drug analysis encompasses tests on raw materials (purity criteria), pharmaceutical or veterinary formulations, and a number of other, more complex matrices such as foods of animal origin, drinks, and foodstuffs that are conducted for clinical, forensic, or veterinary purposes involving a variety of matrices including blood, urine, and tissues. Pharmaceutical analysis is restricted to drug analyses in raw materials and pharmaceutical formulations; in some instances, it also includes clinical analyses. Pharmaceutical analyses involve the determination of not only active components but also impurities, excipients, the stability of active components (and their degradation intermediates or end-products), and other parameters such as content uniformity, solubility, and dissolution rate.

Some spectrophotometric analyses focus on the properties of the target compound (its native spectrum), a chemical derivative, or the product of some separation or sample pretreatment. Direct analyses of target compounds are only possible if the wavelength used is not interfered with by other species or by background absorption; analyses of mixtures of components are also possible with recent developments in chemometrics and derivative spectrophotometry.

The first question to be answered is: what is the wavelength that provides the highest sensitivity and selectivity with the best reproducibility? Finding an answer entails deciding on optimal conditions of pH, solvent, and range of application of the Lambert-Beer law.

The situation is basically the same, albeit technically more complex, when some chemical reaction (e.g., derivatization of the analyte) is required prior to measurement.

Chemical pretreatments may be required due to lack of selectivity and/or sensitivity of direct spectrophotometry. The chemistry of spectrophotometric determinations in pharmaceutical analysis is by now well documented; common procedures are: redox reactions; metal ion chelation reactions for the determination of organic compound or metal ion components; charge transfer complex formation reactions; ion pairing; and diazotization.

If the objective is a quantitative determination by direct spectrophotometry, it suffices to read the absorbance at a given wavelength. By virtue of their simplicity, these methods are more precise than those involving chemical pretreatment. Therefore, if the absorption wavelength and intensity of the analyte are both adequate, pharmacopoeias and compilations of standard methods recommend using this approach. The choice between direct spectrophotometry and chemical derivatization is also influenced by the accuracy required in the result, the purity of the target analytes, and the interferences expected. If the sample allows for it, the solid, once powdered, can be extracted with water or another solvent (usually methanol or ethanol) at an appropriate pH, filtered, and diluted to the required concentration before measuring the absorbance.

### Determination of Pharmaceuticals without Chemical Derivatization of the Analyte

Most pharmaceuticals have a native spectrum without high molar absorptivities at any absorbing wavelength, which leads to mostly quantitation procedures using chemical derivatization of the analyte. Recent literature does not propose spectrophotometric methods based on the native spectrum of the drug, because they result in low sensitivity and can be only utilized when high accuracy is not required.

Another question to be considered is selectivity. The drug (even 'pure' bulk drug) may very often be accompanied by compounds with similar chromophores from different sources, namely, residual starting materials, products of synthesis, degradation products, the spectra of which may resemble closely to that of the analyte. Consequently, the selectivity of direct spectrophotometric methods is insufficient. The choice of solvent and the pH should be considered in connection with the sensitivity and selectivity of these procedures.

Examples include the spectrophotometric method developed to determine 1,4-benzodiazepines, diazepam, bromazepam, and clonazepam in pure forms, pharmaceutical preparations, and biological (urine) fluids measure the absorption spectra in methanolic potassium hydroxide solution; and the quality control of tablets containing mirtazapine is based on the measurement in methanol solution. The weighed and powdered sample is sonicated for

10 min and then made up to volume with methanol. To the aliquots of the filtered extract phosphoric acid is added. The same solvent has also been proposed for the estimation of mefloquine hydrochloride.

### Simultaneous Determinations (Derivative Spectrophotometry and Other Chemometric Approaches)

**Derivative spectrophotometry** The theoretical background is well known; however, its recent applicability is due to the availability of spectrophotometers that are able to scan the complete spectrum in a short time and provide data to the microcomputer to generate the corresponding derivative spectrum.

The analytical applications of derivative spectrophotometry focus on two aspects: background correction, and the resolution of overlapping bands for quantitative analysis and avoiding separation or other sample pretreatment steps. Other goals are to eliminate the effect of turbidity in the sample matrix and to improve spectral resolution.

Derivative spectrophotometry is highly effective for the analysis of mixtures, particularly with the quick recording when diode array spectrophotometers are used. The resolution of a binary mixture, when the spectra of the two compounds are different, requires a simple mathematical treatment of the data obtained at two wavelengths. However, drug mixtures having overlapped spectra require other mathematical treatment such as derivative spectrophotometry.

The resolution of binary mixtures of compounds with overlapping spectra by derivative spectrophotometry is frequently made on the basis of zero-crossing measurements, which is based on the measurement of the absolute value of the derivative spectrum of the mixture at a cutoff value (of wavelength) where the intensity of one of the components of the mixture is zero. At this wavelength intensity is directly proportional to the concentration of the other component.

Most studies deal with the simultaneous determination of binary or even ternary mixtures of drugs with overlapped spectra; or they determine one drug in a formulation by avoiding interferences from other compounds. Less frequent are stability studies in which derivative spectrophotometry is used as a tool for the determination of the drug in the presence of its degradation products. Examples of this include the determination of sumatriptan succinate by using first and second derivative spectra applied to bulk powder, laboratory-prepared mixtures, and a pharmaceutical dosage form; and determination of aceclofenac in the presence of its degradation product,

based on the determination of diclofenac by the third derivative spectrophotometry in pharmaceutical formulations. **Table 1** gives many examples of studied mixtures. Two stability-indicating methods have been developed for the determination of doxazosin mesylate and celecoxib in the presence of their degradation products. One method is based on the use of first derivative spectrophotometry in bulk powder, laboratory-prepared mixtures, and pharmaceutical dosage forms. The other, a derivative spectrophotometric method, is based on the simultaneous determination of amlodipine and its pyridine photodegradation product with spectral measurements on the third-order UV derivative spectrum. The method can be applied usefully to routine quality control of pharmaceutical formulations containing amlodipine and lisinopril in commercial dosage forms.

The purity of aztreonam can be maintained through its reaction with cerium(IV) in acidic medium. The spectrophotometric method involves the quantitation of the amount of ceric equivalent to aztreonam by measuring the absorbance at 317 nm and the corresponding first-derivative value at 284 nm for the blank solution against the reaction solution. It can be applied to the determination of aztreonam in pure form and in the presence of arginine both in laboratory mixtures and in commercial formulations. The determination of imipramine in the presence of iminodibenzyl as an impurity uses a first-derivative ratio spectrum and can be applied to pharmaceutical dosage forms.

Many of the procedures used in derivative spectrophotometry are also used in other chemometric procedures when dealing with the same analytical problem. Examples are (first and second mean, the first and the second derivatives, respectively): progesterone (first, by difference absorbance values at 227.2 and 253.6 nm); vasartan (second, at 205.6 nm); indapamide (first at 252.8 and second at 260.4 nm); ibesartan in the presence of hydrochlorothiazide (first at 263.0 nm); reboxetine (fourth after extraction); astemizole (second and zero crossings); cisapride (first at several wavelengths, e.g., 264 and 300 nm; and the second at 276 and 290 nm); glimepiride (second in dimethylformamide over the range 263.3–268.2 nm by peak to peak, the peak to zero at 268.2 nm, and tangent at 263.3–271.8 nm); mirtazapine (first and second, in methanol solutions over the range 225–360 nm); olanzapine (first at 298 nm); thonzylamine hydrochloride (first at 492 nm); nimesulide (second in different solvents and wavelengths); zinc in formulations (fourth after reaction with 1,2-thiazo-naphthol); lansoprazole (second at 200 and 400 nm); miconazole (second and

after extraction); and, finally, haloperidol in the presence of parabens (first and the zero crossings).

**Chemometric procedures** Simultaneous spectrophotometric determinations on binary or ternary mixtures of drugs in a formulation, and avoiding separation methods and other sample pretreatments, can also be achieved by using chemometric-assisted spectrophotometric procedures other than derivative spectrophotometry. Analyzing synthetic mixtures containing title drugs by this approach has been validated using liquid chromatographic or capillary electrophoresis. The effort devoted to other chemometric methods is less than that devoted to derivative spectrophotometry. Tablets and sugar-coated pills are the formulations generally analyzed.

Studies on binary mixture samples frequently deal with classical least-squares, inverse least-squares, principal component regression and partial least-squares methods. These methods have been used for resolving mixtures of hydrochlorothiazide and spirinolactone in tablets; cyproterone acetate and estradiol valerate; amiloride and hydrochlorothiazide;

mefenamic acid and paracetamol; chlorphenoxamine hydrochloride and caffeine; benazepril hydrochloride and hydrochlorothiazide.

Mixtures of acetylsalicylic acid and ascorbic acid have been studied by using parallel factor analysis and partial least-squares. The former is used for spectral deconvolution, and  $pK_a$  estimation for both acids. The simultaneous determination of fosinopril and hydrochlorothiazide in pharmaceutical formulations consists of extracting both compounds in an aqueous solution, measuring by multiwavelength UV spectrophotometry; hydrochlorothiazide acts as an internal standard to verify the accuracy of the analysis.

Chemometrics has also been applied to solve other problems but not for the quantification of binary mixtures. Principal component analysis (PCA) has been used to plot dissolution curves and provide information about between- and within-batch variations. Differences in level or shape can be observed in the first two principal components (PCs). Irrelevant irregularities, which have a strong influence on the similarity factor, are resolved.

A kinetic spectrophotometric method has been developed for the simultaneous quantitative determination of acetaminophen and phenobarbital in pharmaceutical preparations. The basis of the method was the different kinetic rates of the analytes in a two-step chemical procedure: first the oxidative coupling reaction with 3-methylbenzothiazolin-2-one hydrazone in hydrochloric acid medium and then using Fe(III) as oxidant and continuous absorbance monitoring. An artificial neural network (ANN) coupled with PCA (PC-ANN) has been used to simulate this method.

Spectrophotometric monitoring with the aid of chemometrics has also been applied to more complex mixtures. To solve the mixtures of corticosteroid dexamethasone sodium phosphate and vitamins B<sub>6</sub> and B<sub>12</sub>, the method involves multivariate calibration with the aid of partial least-squares regression. The model is evaluated by cross-validation on a number of synthetic mixtures. The compensation method and orthogonal function and difference spectrophotometry are applied to the direct determination of omeprazole, lansoprazole, and pantoprazole in gastroresistant formulations. Inverse least squares and PCA techniques are proposed for the spectrophotometric analyses of metamizol, acetaminophen, and caffeine, without prior separation. Ternary and quaternary mixtures have also been solved using iterative algorithms.

## Determination Methods with a Prior Chemical Pretreatment

Chemical pretreatment is used to improve the analytical figures of merit with special emphasis on sensitivity and reproducibility. The spectrophotometric determination of pharmaceuticals relies on well-known reaction methodologies such as oxidation of the drug and the formation of metal complexes.

### Redox

Common strong oxidants are used to obtain colored products by acting directly on the pharmaceutical, e.g., Ce(IV), Cr(VI), metavanadate, BrO<sub>3</sub><sup>-</sup>, *N*-bromosuccinimide, and chloramine-T. Direct oxidation of imipramine and desipramine by ammonium metavanadate allows its determination in pharmaceutical dosage forms. The quantitative estimation of 11 phenothiazine drugs in dosage forms is also based on the interaction of these phenothiazine compounds with diphenylamine in presence of *N*-bromosuccinimide and sulfuric acid. Most of the studied phenothiazines yield bluish green products and the color is stable for at least 1 h.

The oxidation of nizatidine is used to develop a kinetic method for the determination of this drug in capsules. The reaction is with ammonium cerium(IV) sulfate in the presence of perchloric acid and the subsequent measurement of absorbance at 314 nm.

Sometimes the proposed method is an 'indirect' procedure to monitor the excess of oxidant or the color change of an auxiliary reagent such as the method described for the assay of azathioprine, either in pure form or in pharmaceutical formulations; the methods are based on the oxidation of the drug with excess *N*-bromosuccinimide or chloramine-T and determining the consumed reagent by the decrease in color intensity of celestine blue or gall-o-cyanine, respectively. Another example is the determination of ascorbic acid in fruit juice and pharmaceuticals on the basis of its inhibition effect on the reaction between hydrochloric acid and bromate. The decolorization of methyl orange due to the reaction products was used to monitor the reaction at 510 nm.

The spectrophotometric determination of the following antibiotics has been performed based on the reactivity with iodine: ampicillin, penicillin V, amoxycillin, cloxacillin, cefadroxil, ceftezoxime, griseofulvin, streptomycin, nicoumalone, and acebutolol hydrochloride. An excess of iodine of known concentration is added to the drug alkaline solution and the unreacted iodine monitored through the decrease in the absorbance of the dye wool fast blue at 540 nm. The determination of pentoxifylline is also based on adding a known excess of standard iodine solution under alkaline conditions and the excess of iodine determined at pH 3.0 with metol-isoniazid (620 nm) or also with wool fast blue (540 nm).

The oxidation of the phenothiazines by a known excess of chromium(VI) and subsequent determination of the unreacted oxidant by interacting with metol and sulfanilic acid resulted in colored species that exhibit maximum absorbance at 530 nm.

In some cases, the redox reaction is one step in the whole determination process. The well-known reductive behavior of ascorbic acid on Fe(III) results in Fe(II) ions that form a chelate with *o*-phenanthroline. This chelate is easily adsorbed on an anion-exchange gel of dextran type. The adsorbent is packed into the spectrophotometer cell and the absorbance of the resin monitored at 567 and 800 nm. The ascorbic acid is determined without any preconcentration in fruit juices, pharmaceutical formulations, human urine, and conservative liquids.

Different oxidizing agents can be tried, e.g., Ce(IV) and Fe(III), for the determination of *p*-aminophenol and acetaminophen in dosage forms and without prior separation. The method is based on the

reaction of *p*-aminophenol at room temperature with sodium sulfide in presence of the oxidant to produce a methylene blue-like dye. The color develops within 10 min and remains stable for at least 3 h.

Spectrophotometric methods for the determination of catecholamine derivatives pyrocatechol, dopamine, levodopa, and methyl dopa have been developed and applied to injections and tablets. One of the methods involves the oxidation of *o*-dihydroxybenzene derivatives by *N*-bromosuccinimide followed by oxidative coupling with isoniazide, leading to the formation of a red-colored product of maximum absorbance at 480–490 nm.

A spectrophotometric procedure for the determination of phenothiazines in pure form and in some pharmaceutical dosage formulations was based on the oxidation of the drug by a known excess of potassium dichromate. The unreacted potassium dichromate was estimated by reacting with excess of Fe(II) and complexing the released Fe(III) with thiocyanate.

### Paired Ionic Compounds

The formation of ion pairs between two ions of relatively large size and low charge – one of which will be the active principle – provides water-insoluble products. The experimental procedure is very simple, but is also slow as the insoluble compounds formed must be extracted with an organic solvent for their spectrophotometric determination. Ion-pairing reactions also provide substantially improved sensitivity and selectivity. Most reported methods of this type use organic counterions to avoid the extraction step. Table 2 gives a representative list of examples.

### Metallic Ion Chelates

These reactions are fast and provide simple experimental procedures, since, unlike ion pairing, they yield water-soluble products. In some cases (e.g., with ternary complexes), the products are made soluble with the aid of a surfactant. However, the

process is relatively simple and highly sensitive; molar absorptivities are adequate for the analysis of pharmaceutical formulations.

**Formation of metallic ion chelates for the determination of organic active principles** Some recent illustrative examples are as follows:

1. The determination in dosage forms of piperazine derivatives, ketoconazole, trimetazidine hydrochloride, and piribedil, by the formation of yellow orange complexes between iron(III) chloride and the drug. The method allows ranges of determination over 1–15, 1–12, and 1–12 mg l<sup>-1</sup>, respectively, and has been applied to different dosage forms.
2. The determination of amoxicilline, ciprofloxacin, and piroxicam in bulk and pharmaceutical preparations has been performed by combining the oxidation character of Fe(III) with the chelation property of Fe(II), affording highly colored complexes. The reagent solutions are: (1) a mixture of 1,10-phenanthroline and iron(III) ammonium sulfate in hydrochloride medium; and (2) 2,2'-bipyridyl and iron(III) ammonium sulfate in hydrochloride medium. The resulting Fe(II) concentration, proportional to the amount of drug present, is monitored by the measurement of absorbances of tris(*o*-phenanthroline) iron(II) or tris (bipyridyl) iron(II) complexes at 510 and 522 nm, respectively.
3. The formation of a chelate compound of strontium with bromopyrogallol red and cetylpyridinium chloride serves to develop a method for the spectrophotometric determination of cetylpyridinium chloride in pharmaceutical products. This indirect procedure is based on the influence of micellar media on the absorption spectrum of the strontium(II)–bromopyrogallol red complex; the formation of the ternary complex is accompanied by an observed increase in absorbance and a bathochromic shift in the maximal absorption of the complex from 555 to 627.5 nm. The optimum pH range for the reaction is 4.0–5.0 and Beer's law is obeyed over the concentration range 0.01–0.07 mg l<sup>-1</sup>.
4. The determination of two fluoroquinolone antibacterials (ciprofloxacin and norfloxacin), either in pure form or in tablets, is possible on the basis of the formation of a ternary complex palladium(II)–eosin–fluoroquinolone in the presence of methyl cellulose as surfactant. The ternary complexes show an absorption maximum at 545 nm and obey Beer's law in the concentration range 3–10 mg l<sup>-1</sup> for both quinolones.
5. The photometric reagent 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol is used for the determination of zirconium; when fosfomycin is added, it

replaces diethylaminophenol by complexing with zirconium. This forms the basis for an indirect spectrophotometric method for fosfomicyn based on ligand exchange and is applied to dosage forms. The detection wavelength is at 605 nm, and the apparent molar absorption coefficient is found to be  $4.59 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$ .

**Determination of metallic ions in pharmaceuticals** Spectrophotometric determination of a metal is present as an active component in dosage forms; it is most suitable for impurities, using atomic

absorption spectrometry for detection. However, the 'classical' formation of a metallic complex with an organic compound, frequently aided by liquid–liquid extraction or the presence of tensoactives, is also used for drugs in pharmaceutical formulations and biological samples. Some examples are given in Table 3.

**Diazotization** A procedure for amine compounds diazotization followed by a coupling reaction of the diazonium ions and phenols to produce strongly colored azo compounds ( $\text{ArN}=\text{NAr}'$ ) by electrophilic substitution. The azo link  $-\text{N}=\text{N}-$  gives a

conjugation of aromatic rings resulting in a large system of  $\pi$  electrons, allowing light absorption into the visible region. The kinetic stability of resulting solutions is high.

The determination of flutamide in either pure form or in its pharmaceutical preparations can be performed with the aid of two different processes: (1) the diazotization of reduced flutamide, followed by coupling with alcoholic iminodibenzyl in acid medium to give a purple-colored product having a maximum at 570 nm; or (2) diazotization of the reduced flutamide and coupling it with 4-amino-5-hydroxy-2,7-naphthalenedisulfonic acid monosodium salt in a buffer medium of pH 12, which gives a red-colored

product presenting a maximum absorbance at 520 nm.

The estimation of catechol and its derivatives such as dopamine hydrochloride, levodopa, methyl dopa, and adrenaline hydrochloride in both pure form and in pharmaceutical formulation is based on the interaction of diazotized sulfanilamide with catechol derivatives in the presence of molybdate ions in acidic medium. Absorbance of the resulting red-colored product is measured at 490 nm for pyrocatechol and at 500 nm for other catechol derivatives. The color reaction is stable for 24–30 h.

The determination of nimesulide also requires the reduction of the group  $\text{NO}_2$  and then diazotization

followed by either coupling with alcoholic iminodibenzyl in acid medium to give a deep blue colored product (600 nm) or coupling with 3-aminophenol in acid medium to produce an orange red colored product with maximum absorbance at 470 nm. This method can be applied either to the pure form or pharmaceutical formulations.

The spectrophotometric determination of folic acid, either in pure form or in its pharmaceutical preparations, is based on the probable diazotization of *p*-aminobenzoylglutamic acid obtained after reductive cleavage of folic acid, followed by either coupling with iminodibenzyl (maximum absorbance at 580 nm) or with 3-aminophenol to produce an orange yellow colored product (460 nm).

The azathioprine is an immunosuppressive antimetabolite drug containing also a nitro group and its diazotization with excess nitrous acid also required the preliminary reduction of the drug. The spectrophotometric monitoring of either the consumed nitrous acid ( $\text{HNO}_2$ ) with cresyl fast violet acetate or by coupling reaction of the diazonium salt formed with *N*-1-naphthylethylenediamine dihydrochloride has been proposed. The reaction shown in Figure 1 depicts the proposed analytical procedure.

A spectrophotometric method for some sulfa drugs starts with the formation of an orange yellow colored azo product by the diazotization of sulfonamides and is followed by a coupling reaction with 3-aminophenol in aqueous medium. The absorbance of the resulting orange yellow azo product is measured at 460 nm and the product is stable for 6 days at 27°C. The method is successfully used for the determination in various pharmaceutical preparations of the sulfonamides dapsons, sulfathiazole, sulfadiazine,

sulfacetamide, sulfamethoxazole, sulfamerazine, sulfaguanidine, and sulfadimidine. The proposed reaction mechanism is depicted in Figure 2.

Another method for the determination of sulfa drugs is based on the formation of a violet-colored azo product by the diazotization of sulfonamides, followed by a coupling reaction with iminodibenzyl in alcohol medium. Absorbance of the resulting violet azo product is measured at 570–580 nm and is stable for 24 h at 27°C. Beer's law is obeyed in the concentration range of 0.05–6.0 ppm at the wavelength of maximum absorption. The method is successfully employed for the determination of sulfathiazole, sulfadiazine, sulfacetamide, sulfamethoxazole, sulfamerazine, sulfaguanidine, and sulfadimidine. The proposed reaction mechanism for the formation of the violet azo dye is shown in Figure 3.

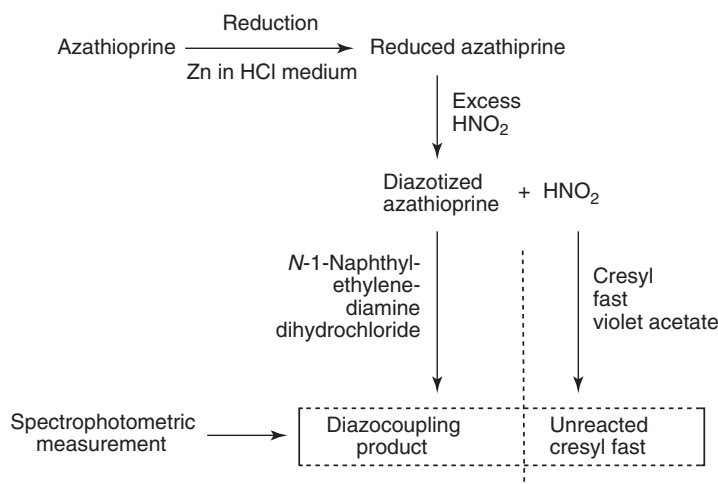

### Charge Transfer Complexes

Charge transfer complexes have high molar absorptivities and are produced when one reagent is an electron donor and the other is an electron acceptor. Light absorption is based on an electronic transition from the donor to an associated orbital of the acceptor. As a consequence, the excited electronic state is an internal redox process.

The active pharmaceutical ingredient should be the donor and the analytical challenge is to find a suitable acceptor. The resulting reactions is very quick and the compound finally formed is dependent on the polarity of the solvent (Table 4).

### Other Chemical Derivatization Procedures

Procedures not included in the preceding sections and having a potential for derivatization are the use

**Figure 1** Analytical procedure for diazotization.

**Figure 2** Reactions in diazotization of sulfonamides.

**Figure 3** Reaction depicting the formation of violet azo dye.

of the light (more usual in dynamic flow methods) and classical titrimetric procedures.

The use of light as a 'reagent' is advantageous as regards the reproducibility of the process, the 'selectivity' of the reagent (irradiation wavelength), and its 'sensitivity' (lamp power). As a result, the photodegradation of organic compounds to photo-fragments gives improved spectrophotometric properties.

The irradiation of some sulfa compounds – such as sulfacetamide, sulfadiazine, sulfaguanidine, sulfamerazine, sulfamethoxazole, and sulfamethizole – gives an absorption band with the maximum at 332 nm.

With regards to spectrophotometric titrimetry, the chloride (hydrochloride) content in a drug can be determined by titration with mercuric nitrate, using a diphenylcarbazone–Bromothymol Blue mixture as indicator. For its spectrophotometric determination, a solution of the Hg(II)–diphenylcarbazone complex is titrated with the unknown sample (pharmaceutical formulation) and the absorbance of the resulting complex at 540 nm – which is decreased as a result of the diphenylcarbazone being displaced by the chloride present in the sample – is monitored.

### Structure–Spectra Correlation (Qualitative Analysis)

If the objective is identification (qualitative analysis), it suffices to compare the spectrum of the analyte with that of a standard, both recorded in the same solvent and at an identical pH. This is not the main application of UV–Vis spectrophotometry as the best results in this context are provided by spectroscopic methods considered more effective for the study of the molecular structure of organic compounds (infrared, nuclear magnetic resonance, mass spectrometry, and X-ray diffraction). However, UV–Vis spectrophotometry is a source of relevant supplementary information that helps in the elucidation of molecular structures of drugs, impurities, metabolites, intermediate compounds of degradation, etc.

UV–Vis absorption is essentially a classical quantitative tool for organic compounds, but a good level

Phenobarbital (1), thiopental (2), methohexital, phenytoin	Iodine; 7,7,8,8-tetracyanoquinodimethane; 2,3-dichloro-5,6-dicyano-1,4-benzoquinone; 2,3,5,6-tetrachloro-1,4-benzoquinone; 2,3,5,6-tetrafluoro-1,4-benzoquinone; 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone; tetracyanoethylene-2,4,7-trinitro-9-fluorenon (depending on the solvent polarity)
Haloperidol, droperidol	Iodine (in 1,2-dichloroethane); 2,4,7-trinitro-9-fluorenon (in 1,2-dichloroethane); 7,7,8,8-tetracyanoquinodimethane (in acetonitrile); 2,3-dichloro-5,6-dicyano- <i>p</i> -benzoquinone (in methanol); tetracyanoethylene (in acetonitrile); 2,3,5,6-tetrabromo-1,4-benzoquinone (in methanol)

of information about the correlation of molecular structure and spectra is required for empirical analysis. When the formula of the compound is under study, information obtained from the structure–spectra correlation can help predict several facts: the compound possesses a sufficiently strong absorption band; part of the spectrum in which the band (or bands) nesting occurs; and possible overlap with any interference present in the formulation. The analytical result is the information required to predict the possibility of spectrophotometric determination in a given sample matrix. The structure–spectra correlation is basically empirical and qualitative. If the objective is only the identification of a pharmaceutical active ingredient, all that is required is an agreement of the wavelength of the absorption maximum (minimum) with that of a standard sample. The determination of the specific absorbance at a given wavelength should only be given as much importance as the measurement of any other physical constant (melting point, density, specific optical rotation), as the absorbance value does not give conclusive evidence for assessing the quality of the bulk material.

Databases of spectral details include the complete spectrum (spectral atlases), wavelength of relative maximum (or minimum), and molar absorption coefficients. Basically, few factors should be required to be familiar with the relationship of the molecular structure and the spectrum of a given compound; factors such as the intensity of the absorption bands, the shape of the band, and the wavelength interval of the band. Additionally, the medium is

very important, which shows the critical influence of any solvent on the spectrum of the pharmaceutical.

This article is reproduced from the first edition, pp. 4748–4760, © 1995, Elsevier Ltd., with revisions made by the Editor.

### Introduction

Sensitive and selective qualitative tests based on chemical reactions using small amounts of samples and reagents, often in single drops, are referred to as 'spot tests'. The procedure is the ultimate in simplicity. The target is to reach the utmost sensitivity and selectivity with a minimum of physical and chemical operations. Separations and conditioning reactions are generally integrated into the test procedure so that the final test becomes a single operation that can be applied directly for the identification of the substance in question.

The systematic development of spot test methods of analysis occupied Fritz Feigl in Vienna and Rio de Janeiro for half a century up to ~1970. Although in the past few decades chemical analysis has undergone a formidable process of sophistication with the development of advanced instrumental tools, there has been at the same time a contrary trend toward simplification in selected areas in the form of simple, rapid, and inexpensive spot and screening tests. Commercial companies are selling large numbers of compact spot test systems for the rapid establishment of the presence or absence of particular substances in clinical, food, water, soil, and forensic samples. The tests are essentially qualitative, but often can be semiquantitative if procedures as simple as visual comparison of color intensity are used.

### Techniques

The choice of techniques to be followed is generally dictated by the nature of the sample and the reagents

available. The tests are usually run by using one of the following techniques:

- (1) bringing together one drop each of the test solution and the reagent on porous or non-porous supporting surfaces such as paper, glass, or porcelain;
- (2) placing a drop of the test solution on a medium impregnated with appropriate reagents (filter paper, gelatin);
- (3) placing a drop of the reagent solution on a small quantity of the solid specimen (pulverized particles, evaporation or ignition residues);
- (4) subjecting a drop of reagent, or a strip of filter paper, to the action of gases liberated from a drop of test solution or from a minute quantity of the solid specimen.

### Equipment

The equipment required for simple spot test analysis is made of glass, porcelain, plastic, and metal. A classical spot test laboratory setup consists of assorted small sizes of beakers, volumetric flasks, suction flasks, Conway cells, crystallizing dishes, evaporating dishes, separating funnels, extracting pipettes, fritted glass crucibles, graduated cylinders, pipettes, burettes, weighing bottles, storage bottles, vials, test tubes, centrifuge tubes, microscope slides, white and black porcelain dishes, and spot plates. Tweezers and spatulas, microburners, are essential too. A balance, pH meter, ultraviolet (UV) lamp, and small centrifuge should also be available.

### Tests for Cations

It is often possible to carry out conclusive tests with as little as one drop of dilute sample solution, even though considerable concentrations of other substances are present. This possibility permits the microchemical accomplishment of the so-called 'ultimate' analysis, which demands only a decision as to the presence or absence of a particular substance. In

spectrophotometric determination of sulfonamide derivatives. *European Journal of Pharmaceutics and Biopharmaceutics* 53(2): 187–192.

Ammonium $\text{NH}_4^+$	Red litmus paper	After liberation of ammonia with NaOH	Acid–base indicator	Blue color	Volatile bases, e.g., amines	0.01
Antimony $\text{Sb}^{3+}$ (i.e., $\text{SbO}_3^{3-}$ )	Filter paper impregnated with 5% molybdophosphoric acid	After addn of a test soln, hold paper over steam	Molybdenum blue formation	Blue color	$\text{Sn(II)}$	0.2
Arsenic $\text{As}^{3+}$ (i.e., $\text{AsO}_3^{3-}$ )	Silver nitrate, 1% aqueous soln	Test soln warmed with a few drops of $\text{NH}_3$ and a drop of 10% $\text{H}_2\text{O}_2$ in a test tube; acidified, and reagent added	Silver arsenate formation	Red–brown ppt	Chromates and $\text{Fe(CN)}_6^{3-}$	6
Barium $\text{Ba}^{2+}$	Sodium rhodizonate 0.2% aqueous soln	Neutral or slightly acidic test soln + reagent on filter paper	Complex formation	Red–brown ppt	$\text{M}^{2+}$	0.25
Beryllium $\text{Be}^{2+}$	Morin + EDTA	Ammoniacal	Complex formation	Yellow–green fluorescence		0.07
Bismuth $\text{Bi}^{3+}$	Cinchonine + iodide	Slightly acidic, on filter paper impregnated with reagent	Ion pair formation with $\text{BiI}_4^-$	Orange–red ppt	$\text{Cu}^{2+}$ ; $\text{Pb}^{2+}$ ; $\text{Hg}^{2+}$	0.14
Cadmium $\text{Cd}^{2+}$	Iron(II)–bipyridyl iodide	Weakly acidic, neutral, or ammoniacal test soln on filter paper	Ion pair formation with $\text{CdI}_4^{2-}$	Red ppt	$\text{Hg}^{2+}$ ; $\text{Sn(II)}$ ; $\text{Sb(III)}$ ; $\text{Bi}^{3+}$	0.05
Calcium $\text{Ca}^{2+}$	Glyoxal bis(2-hydroxyanil)	Neutral or acidic test soln. After reaction add NaOH and $\text{Na}_2\text{CO}_3$ ; extract with chloroform	Complex formation	Red color in the chloroform layer	$\text{Cd}^{2+}$	0.05
Chromium $\text{Cr}^{3+}$	Diphenylcarbazide	First add potassium peroxodisulfate and $\text{AgNO}_3$ . After 2–3 min add reagent	Complex formation	Violet color	$\text{Hg}^{2+}$ ; $\text{MoO}_4^{2-}$ ; $\text{VO}_3^-$	0.8
Cobalt $\text{Co}^{2+}$	Nitroso-R salt	Dowex-1 XI ion exchange resin treated on spot plate with reagent. $\text{CH}_3\text{COONa}$ and the sample. After 5 min add $\text{HNO}_3$ and heat on water bath	Complex formation	Red color	None	0.003
Copper $\text{Cu}^{2+}$	2,2'-Biquinolyl (cuproin)	Acidic test soln treated with hydroxylamine to reduce $\text{Cu(II)}$ to $\text{Cu(I)}$	Complex formation	Purple–red color	None	0.05
Gold $\text{Au}^{4+}$	<i>p</i> -Dimethylaminobenzylidene-rhodanine	Neutral or weakly acidic test soln placed on reagent paper	Formation of $\text{Au(I)}$ complex	Violet ppt	$\text{Ag}^+$ ; $\text{Hg}^{2+}$ ; $\text{Pd}^{2+}$	0.1
Iron $\text{Fe}^{2+}$	2,2'-Bipyridyl		Complex formation	Red color	None	0.03
Lead $\text{Pb}^{2+}$	Dithizone in $\text{CHCl}_3$	Test soln shaken with cyanide (CARE) and reagent soln	Complex formation	Red $\text{CHCl}_3$ layer	Specific	0.04
Magnesium $\text{Mg}^{2+}$	Quinalizarin	Mix test soln and reagent. Add NaOH soln until color changes to violet	Lake formation	Blue ppt (blank: blue–violet soln)	Metal ions precipitated at alkaline pH	0.25

Manganese Mercury $\text{Hg}^{2+}$	Periodate + tetrabase Diphenylcarbazone	Dilute acetic acid Test soln in $\text{HNO}_3$ placed on reagent paper	Oxidation to $\text{MnO}_4^-$ Complex formation	Deep blue color Violet–blue ppt	$\text{Cr}^{3+}$ Selective in the absence of chromate and molybdate	0.001 0.2
Molybdenum $\text{Mo(VI)}$ $(\text{MoO}_4^{2-})$	<i>o</i> -Hydroxyphenylfluorone	Acidic, test on filter paper. Add KF to mask interferences		Carmine red stain	None	1.7
Nickel $\text{Ni}^{2+}$	Dimethylglyoxime	Test soln and reagent placed on filter paper, held over $\text{NH}_3$	Complex formation	Red ppt	$\text{Pd}^{2+}$ ; $\text{Fe}^{2+}$ ; $\text{Co}^{2+}$	0.16
Palladium $\text{Pd}^{2+}$	Nickel-dimethylglyoxime paper	Treat with drop of test solution, wash with dil. acid	Protective layer formed over Ni complex	Red stain	No data	0.05
Platinum $\text{Pt(IV)}$	(1) Saturated aqueous $\text{TlNO}_3$ ; soln	Reagent (1) on filter paper. Add test soln. Wash with $\text{NH}_3$ and treat with reagent (2)	Reduction to Pt element	Orange–red stain	None	0.025
Potassium $\text{K}^+$	(2) $\text{SnCl}_2$ in strong HCl 0.05% $\text{AgNO}_3$ soln and a tiny crystal of $\text{Na}_3[\text{Co}(\text{NO}_2)_6]$	Neutral or acetic acid test soln placed on black spot plate with a drop of reagent and crystal	Precipitation	Yellow ppt	$\text{Li}^+$ ; $\text{Ti}^+$ ; $\text{NH}_4^+$	4
Silver $\text{Ag}^+$	Filter paper impregnated with saturated acetone solution of <i>p</i> - dimethylaminobenzylidene– rhodanine	Slightly acidic test soln	Complex formation	Red–violet spot against yellow–brown background	$\text{Hg}^{2+}$ ; $\text{Au(III)}$ ; $\text{Pt}^{2+}$ ; $\text{Pd}^{2+}$ ; $\text{Cu}^{2+}$	0.02
Sodium $\text{Na}^+$	Zinc uranyl acetate	Neutral or acetic acid test soln mixed on a black spot plate with reagent soln	Insoluble salt precipitated	Fluorescent, yellow ppt	High cone, of Li and K	2.5
Strontium $\text{Sr}^{2+}$	Sodium rhodizonate soln, filter paper impregnated with saturated soln of potassium chromate	Test soln is placed on paper. After 1 min a drop of reagent is added	Complex formation	Brown–red	Selective among the alkaline-earth metals	3.9
Tin $\text{Sn(II)}$	Ammonium molybdophosphate on filter paper	Test soln. placed on reagent paper	Reduction by $\text{Sn(II)}$	Blue	No data	0.03
Tungsten $\text{W(VI)}$ $(\text{WO}_4^{2-})$	2,4'-Diaminodiphenyl hydrochloride in HCl	Test soln mixed with reagent	Precipitation	White ppt	Molybdate in high conc.	6
Uranium $\text{U(VI)}$ $(\text{UO}_2^{2+})$	8-Quinolinol (oxide) soln in ethanol	Precipitate interfering ions $(\text{NH}_4)_2\text{CO}_3$ soln. Filtrate treated with reagent on spot plate	Complex formation	Red–brown ppt	None	10
Vanadium $\text{V(V)}$ $(\text{VO}^{3+}; \text{VO}_2^+)$	2-(Salicylidene-imino) benzoic acid on filter paper	Drop of acidic sample spotted on the paper	Complex formation	Violet stain	None	0.2
Zinc $\text{Zn}^{2+}$	Dithizone in $\text{CCl}_4$	Drop of test soln mixed on a watch glass with a drop of $2 \text{ mol l}^{-1}$ $\text{NaOH}$ and a few drops of reagent. Evaporate the $\text{CCl}_4$	Complex formation	Raspberry red soln (a colored ppt is disregarded)	None	5
Zirconium $\text{Zr}^{4+}$	Neothorin (Arsenazo I)	Drop of sample in conc. HCl treated with reagent	Complex formation	Blue–violet ppt	$\text{Hf}^{4+}$	3

ppt, precipitate; soln, solution.

many cases this can be achieved successfully without a preliminary separation by application of selective reactions.

It is also advisable to try out the reaction with pure solutions containing a series of concentrations of the substance to be detected.

Some selected examples of spot tests for cations are described in **Table 1**. Features such as the selectivity of the reaction, its sensitivity, the availability of the reagents, and simplicity of execution are the main parameters upon which the selection is based. The short descriptions given may be enough to allow the tests to be carried out, but Feigl's books should be consulted for more details and a deeper understanding of the reactions and to solve acute interference problems.

## Tests for Anions

Tests for anions are usually made in solutions that contain cations only of the alkali metals and thallium(I). This is achieved through preparation of sodium carbonate extracts by treating the test solutions with sodium carbonate and removing the resulting precipitate.

The metal cations in these procedures are transformed into their slightly soluble carbonates and hydroxides and are thus separated from the water-soluble alkali salts of the anions. Thallium(I), whose carbonate is soluble, is an exception. Spot reactions to detect the various anions can be successfully made on drops of the sodium carbonate extract.

Selected spot tests for anions are given in **Table 2**.

## Tests for Organic Compounds

Organic compounds may be detected by testing for a particular functional group (e.g., ketone, nitro compound) or for individual compounds. Tests for the more common functional groups are summarized in **Table 3**. Specific tests for some important individual compounds are given in **Table 4**. In the majority of cases, there is some previous knowledge about the origin of the sample, which may replace the necessity for complete specificity.

## Applications

Parallel to the advance toward instrumental sophistication, a trend toward simplification has been seen in some marginal, selected areas in the form of simple, rapid, and inexpensive spot and screening tests. A screening test is defined as a simple method that provides a sufficient answer the analytical question

with a minimum expenditure of time and money. It would be wasteful to devote resources to attaining precision or accuracy several magnitudes beyond that necessary in clinical urine analysis, for example, when pathological changes in the composition of urine are evidenced by a simple spot test.

The use of spot and screening tests is a marginal one; the margin, however, is quite significant. For the exact determination of most chemical substances, complex analytical procedures are unavoidable.

Commercial companies in the United States, Europe, and Japan are selling vast quantities of compact spot test systems to solve problems in clinical analysis, in control tests of air quality, in food, water, and soil analysis, and in forensic laboratories.

Simple, compact, and inexpensive analytical devices have been elaborated for semiquantitative evaluation of certain elements and compounds where such an approximated result has diagnostic value, in at least the first stage of the examination.

In the remainder of this article, selected examples of applications of spot tests are given.

## Clinical Applications

### Glucose

The first rapid tests in urine analysis were carried out in the 1940s by adding tablets to urine samples. The test for sugar was refined in the Clinitest<sup>®</sup> reagent tablets (Ames Co., Elkhart, IN). They are an ingenious adaptation of the alkaline copper reduction test in self-heating tablet form. Each tablet contains copper sulfate, sodium carbonate, and citric acid. Sodium carbonate and citric acid form an effervescent couple, which facilitates the rapid dissolution of the tablet and generates a little heat. Much more heat is liberated by the dissolution of sodium hydroxide and its partial neutralization by citric acid. In the alkaline medium, the sugar reduces the blue copper(II) sulfate solution to reddish insoluble copper(I) oxide. The carbon dioxide displaces the air above the reaction and prevents reoxidation of the copper(I) oxide during the test. The color of the mixture indicates the proportion of sugar in urine.

The Clinistix<sup>®</sup> (Ames Co.) is an enzymatic glucose test based on the activity of the enzyme glucose oxidase that uses dry-reagent chemical technology. A firm plastic strip, to which a stiff absorbent cellulose area is affixed, is impregnated with a buffered mixture of glucose oxidase, peroxidase, and *o*-toluidine. In the first stage of the reaction, glucose is oxidized by atmospheric oxygen in the presence of glucose oxidase to gluconic acid and hydrogen peroxide,

**Table 2** Selected spot tests for anions

Anion	Reagent	Test conditions	Reaction type	Visible change	Interference	Limit of identification ( $\mu\text{g}$ )
Azide $\text{N}_3^-$	Iron(III) chloride	Hydrazoic acid liberated in a test tube by addition of dilute HCl to test soln. Filter paper wetted with reagent soln covers the tube	Iron(III) azide formation	Red	$\text{SO}_4^{2-}$ , $\text{S}_2\text{O}_3^{2-}$	2.5
Borate $\text{BO}_2^{3-}$	Benzoin	Test soln evaporated to dryness with NaOH. After cooling add reagent	Fluorescent complex formed	Yellow–green	Chromate, periodate, peroxodisulfate, and hexacyanoferrate(III) must be reduced	0.04
Bromate $\text{BrO}_3^-$	Sulfanilic acid	Test soln and $\text{HNO}_3$ mixed with reagent	Selective oxidation to form azo compound	Violet turning yellow–brown	Selective in the presence of chlorate and iodate	5
Bromide $\text{Br}^-$	(1) Fluorescein in ethanol  (2) Acetic acid–hydrogen peroxide	Test soln placed on filter paper spotted with reagent (2). After drying the spot is treated with reagent (1)	Tetrabromofluorescein (eosin) formation	Red color produced		0.3
Carbonate $\text{CO}_3^{2-}$	Uranyl acetate soln treated with some drops of potassium hexacyanoferrate(II)	Sample mixed on a spot plate with reagent	Demasking of uranyl hexacyanoferrate(II)	Decoloration of brown solution	Phosphate	0.4
Chlorate $\text{ClO}_3^-$	Saturated manganese(II) sulfate and syrupy phosphoric acid (1:1 mixture, v/v)	Test soln and reagent mixture briefly warmed over a microburner and allowed to cool	Formation of a complex manganese (III) phosphate	Violet	Periodate	0.05
Chloride $\text{Cl}^-$	(1) Soln of 8-quinolinol in acetic acid (2) $\text{H}_2\text{O}_2$ + dilute acetic acid	Test soln warmed with both of the reagent solns and $\text{HNO}_3$ and $\text{AgNO}_3$ soln added	Reagent binds all halogens but chlorine	Colorless ppt		2
Chlorite $\text{ClO}_2^-$	$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ soln and $0.1 \text{ mol}^{-1} \text{ NaOH}$	Reagent solns mixed with the test soln and heated in a water bath ( $40\text{--}50^\circ\text{C}$ ) for a few min	Formation of Ni(III) or Ni(IV) oxides	Black specks	None from chlorate, perchlorate, bromate, iodate or periodate	1
Cyanate $\text{OCN}^-$	Hydroxylammonium chloride and $\text{FeCl}_3$ soln	Test solution mixed with both reagents	Resulting hydroxyurea forms complex with $\text{Fe}^{3+}$	Transient violet color	$\text{SCN}^-$	30
Cyanide $\text{CN}^-$	<i>p</i> -Benzoquinone in dimethylsulfoxide	Sample mixed with the reagent	Unknown	Blue–green fluorescence	None	0.2
Fluoride $\text{F}^-$	Alizarin complexan buffered to pH 4.3 and cerium(III) nitrate soln	Sample mixed with the reagents	Ternary complex formation with alizarin complexan – Ce(III) chelate	Color changes from red to lilac blue	None	0.2

Continued

**Table 2** Continued

Anion	Reagent	Test conditions	Reaction type	Visible change	Interference	Limit of identification ( $\mu\text{g}$ )
Hexacyanoferrate(III) $[\text{Fe}(\text{CN})_6]^{3-}$	$\text{ZnCl}_2$ in ethanolic soln saturated with tetrabase	Weakly acidic test soln mixed on filter paper with the reagent	Oxidation to the quinoidal dyestuff	Blue	Chromate, dichromate, permanganate	1
Hexacyanoferrate(II) $[\text{Fe}(\text{CN})_6]^{4-}$	2,2'-Bipyridyl with several milligram of amidomercury(II) chloride	Neutral or sodium carbonate-containing test soln warmed with the reagent	Demasking of $[\text{Fe}(\text{CN})_6]^{4-}$	Red	Not hexacyanoferrate(III)	0.2
Hypohalite $\text{ClO}^-$ , $\text{BrO}^-$ , $\text{IO}^-$	Filter paper impregnated with Safranin O	Test soln dropped onto the paper and washed in water	Possibly an oxidative decomposition of the dye	Violet on the red paper	Hexacyanoferrate(III)	0.5 ( $\text{ClO}^-$ , $\text{BrO}^-$ ); 2.5 ( $\text{IO}^-$ )
Iodate $\text{IO}_3^-$	<i>p</i> -Aminophenol hydrochloride soln	Test soln mixed with the reagent	Selective oxidation to an indamine dye	Violet coloration	Periodate interferes; bromate and chlorate do not	0.5
Iodide $\text{I}^-$	Acetic acid and $\text{KNO}_2$ soln	Starch-containing filter paper is treated with acetic acid, test soln and $\text{KNO}_2$ soln in succession	Oxidation to $\text{I}_2$ , formation of colored compound with starch	Blue	Cyanide	0.025
Nitrite $\text{NO}_2^-$	Diphenylamine in conc. $\text{H}_2\text{SO}_4$	Test soln containing interfering oxidants taken to dryness, heated to 400–500°C and redissolved in water. Test soln is added to the reagent	Oxidation to a quinoida compound	Blue color	Chromate, vanadate, molybdate, antimony(V)	0.5
Nitrite $\text{NO}_2^-$	Sulfanilic acid in acetic acid and 1-naphthylamine oxalate impregnating a filter paper	Neutral or acetic acid test soln dropped on the reagent paper	Diazotization and azo dye formation	Blue–violet color	None	0.00005
Perchlorate $\text{ClO}_4^-$	Filter paper impregnated with thio-Michlers ketone	Take neutral or weakly acidic test soln to dryness with a drop of 2% $\text{CdCl}_2$ soln. Heat on a microburner, while covered with reagent paper	Chlorine formation	Yellow reagent paper turns blue	Halogenates and nitrates eliminated by fuming with HCl	0.1
Periodate $\text{IO}_4^-$	(1) Manganese(II) sulfate and syrupy phosphoric acid	Sample mixed with reagent (1) in a small porcelain dish	Formation of complex manganese(III) phosphate anions	Violet color which is intensified by addition of reagent (2)	Peroxodisulfate, chlorate	5
	(2) Diphenylcarbazine, ethanolic soln	Warmed briefly over a microburner and allowed to cool before adding reagent (2)				
Permanganate $\text{MnO}_4^-$	Cellulose in a thick fillet paper	Neutral or slightly acidic test soln soaked into the paper. Wait 3 min, then wash the paper with water	Reduction of $\text{MnO}_4^-$ to $\text{MnO}_2$ by cellulose	Brown circular stain		0.3 (in presence of 20 mg of $\text{K}_2\text{CrO}_4$ )

Peroxodisulfate $\text{S}_2\text{O}_3^{2-}$	(1) NaOH soln	Test soln and reagents (1) and (2) in succession are placed on a spot plate	Oxidation of $\text{Ni}(\text{OH})_2$ to $\text{NiO}(\text{OH})_2$	Black or grey ppt	$\text{H}_2\text{O}_2$	2.5
Phosphate $\text{PO}_4^{3-}$	(2) $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ soln Ammonium molybdate soln and ascorbic acid soln	Acidic test soln placed on filter paper, followed by a drop of each of the reagent solns. The paper is held over $\text{NH}_3$	Formation of molybdenum blue	Blue stain	$\text{H}_2\text{O}_2$ , oxalate, fluoride, silicate	1.25
Pyrophosphate ( $\text{P}_2\text{O}_7^{4-}$ ) and polyphosphates	Iron(III) perchlorate soln and ammonium thiocyanate soln, freshly prepared	Sample on filter paper sprayed with the reagents	Demasking of the iron(III) thiocyanate complex	White spot on pinkish background	Phosphate and its esters do not react	30 (as P)
Silicate $\text{SiO}_4^{4-}$	(1) Ammonium molybdate soln in $\text{HNO}_3$ (2) Ascorbic acid soln	Test soln mixed with reagent  (1) Supernatant liquid transferred to a microcrucible and gently warmed. After cooling, 1% oxalic acid soln added, followed by reagent (2) and sodium acetate soln	Formation of molybdenum blue	Blue color	1.5 mg $\text{P}_2\text{O}_5$ does not interfere	12
Sulfate $\text{SO}_4^{2-}$	(1) $\text{Ba}(\text{NO}_3)_2$ soln	Weakly acidic test soln spotted on filter paper which has been treated successively with each of reagents (1), (2), and (3)	Demasking of Ba-rhodizonate and formation of silver rhodizonate	Red-brown ppt turning violet	Sulfite, sulfide, and thiosulfate do not interfere	0.3
Sulfide $\text{S}^{2-}$	(2) Sodium rhodizonate soln (3) Silver nitrate soln Sodium azide-iodine soln	Sample and reagent mixed on a watch glass	Catalytic acceleration of the reaction between the two components of the mixture	Brown color of iodine disappears gradually and bubbles of nitrogen appear	Thiosulfate, thiocyanate	0.3
Sulfite $\text{SO}_3^{2-}$	(1) Sodium azide soln	Reagent (3) placed on filter paper and spotted with reagent (1). A violet stain forms. Test soln (pH 5–6) and reagent (2) are added	Acceleration of the slow auto-oxidization of $\text{Co}(\text{II})$ -azide complex by sulfite	A light yellow color changes to blue		0.5
Thiocyanate $\text{SCN}^-$	(2) <i>o</i> -Tolidine in acetic acid soln (3) $\text{CoCl}_2$ soln Sodium azide-iodine solution (see sulfide)	Possible interferents (sulfide, thiosulfate) precipitated by addition of $\text{HgCl}_2$ . Reagent added to the clear supernatant liquid	Catalysts of the iodine-azide reaction	Brown color forms; bubbles of nitrogen develop	None	10

ppt, precipitate; soln, solution.

**Table 3** Detection of functional groups

Functional group	Reagent	Procedure	Visible change	Remarks	Identification limit ( $\mu\text{g}$ )
Aromatic compound	Freshly prepared, 0–2 ml formaldehyde in 10 ml conc. $\text{H}_2\text{SO}_4$	On a spot plate mix with a drop of the test solution	Red, green, brown–orange color development	Blank test with sulfuric acid alone is necessary	2–50
Alcohols (primary, secondary, and tertiary)	1 mg vanadium treated with 1 ml 2.5% 8-quinolinol in 6% acetic acid, shaken with 30 ml benzene	Mix reagent with the test solution, heat in a water bath at $60^\circ\text{C}$	Red color appears after 6–8 min	Reagent solution keeps 1 day	5–20
Secondary alcohols	2% solution of sulfur in carbon disulfide	Heat with sample in a microtest tube; cover mouth of tube with lead acetate paper	Black or brown stain on the paper	Hydrogen sulfide results	10–200
Phenols (volatile)	Filter paper impregnated with a saturated benzene solution of 2,6-dichloroquinone-4-chloroimide	Heat sample in microtest tube at $150^\circ\text{C}$ ; cover mouth of tube with reagent paper. After several min hold reagent paper over ammonia vapor	Blue stain	The phenol must have a free <i>para</i> position	0.3–1
Phenols	(1) Freshly mixed oxalic acid and hexamine  (2) Hydrazine sulfate boiled with sodium acetate in water	Mix reagent (1) and 1 drop of ethanol. Heat to $150\text{--}160^\circ\text{C}$ for 1–2 min. After cooling add a drop of reagent (2). Examine on filter paper	Blue–green fluorescence	No response is given by 2,4- and 2,6-dimethylphenol	0.25–5
Aliphatic polyhydroxides	(1) 5% potassium periodate  (2) 10% sulfuric acid (3) Saturated sulfurous acid (4) 0.1% fuchsin solution; $\text{SO}_2$ passed until the color is discharged	In a microcrucible mix test solution with reagents (1) and (2). Stand for 5 min. Excess periodic acid is reduced with reagent (3) and treated with a drop of reagent (4)	Red to blue color	Citric acid, inositol, pentaerythritol, pentacetylglucose, acetylcellulose do not react	2.5–100
Aldehydes (aliphatic and aromatic)	Pure indole freshly dissolved in pure conc. $\text{HCl}$	Test solution treated with reagent in boiling water	Pink to orange color		$10^{-4}$ –20
Aliphatic aldehydes and ketones	$\text{CuSO}_4$ and an alkaline solution of sodium potassium tartrate (Fehling's solution)	Sample added to reagent solution in a test tube and immersed in boiling water	Dark red crystalline ppt		5–25
Aromatic aldehydes	Solid <i>N,N</i> -dimethyl- <i>p</i> -phenylenediamine	Test solution mixed with reagent and warmed in a water bath	Red color		0.05–100
Ketones	Alcoholic <i>m</i> -dinitrobenzene solution; saturated methanolic potassium hydroxide	Reagents mixed, sample added, and warmed to $70\text{--}80^\circ\text{C}$	Violet–red color		5–200

Carboxylic acids	(1) Thionyl chloride	Solid analyte is treated with reagent (1), and is evaporated almost to dryness. Reagent (2) is added, the mixture made basic to litmus with alcoholic alkali, acidified with reagent (3) and treated with reagent (4)	Color varies from brown–red to dark violet	Positive responses also given by citric and thioacetic acids	10–33
Alkyl esters of carboxylic acids	(2) Saturated alcoholic hydroxylammonium chloride (3) 0.5 mol l <sup>-1</sup> hydrochloric acid (4) 1% aqueous iron(III) chloride (1) Very small piece of metallic sodium (CARE!)	Add to reagent (1) on a spot plate a benzene solution of the ester and reagent (2). After 1–2 min add a drop of water	Violet color		5–10
Ethers	(2) 2.5% benzene solution of dinitrobenzene (1) 5% aqueous copper ethylacetoacetate	Test solution heated in glycerol bath to 230°C. The mouth of the test tube is covered with a disk of filter paper, moistened by reagents (1) and (2)	Blue color	Peroxide formation	20
Amines (aliphatic, aromatic, and heterocyclic)	(2) 5% chloroform solution of tetrabase 5% dimethylsulfoxide solution of 1,3,5-trinitrobenzene	Mix test solution with reagent	Various colors	Complex formation. Glycine does not react	5–25
Primary and secondary amines (aliphatic and aromatic)	1% Dimethylaminocinnamaldehyde dissolved in methanol/trichloroacetic acid	Reagent solution placed on filter paper which is then spotted with ether solution of the amine. Heat at 100°C for 3 min	Primary amines, blue; secondary amines, purple	Schiff base formation	0.02–1.7
Primary and secondary amines (aliphatic)	(1) 1:1 mixture of ethanol:carbon disulfide	Alcoholic test solution mixed with reagent (1). After 5 min reagent (2) is added	Evolution of nitrogen gas	Dithiocarbamate formation and its catalytic action on reagent (2)	1–250
Aliphatic amines	(2) Iodine–sodium azide solution Filter paper impregnated with 2% diphenylcarbazide in formaldehyde	Test solution placed on reagent paper	Pink–violet color	No reaction in the absence of filter paper	0.3–1.6
Aliphatic secondary amines	(1) 5% aqueous copper sulfate solution	Acidic test solution added to reagent (1), made basic with ammonia and shaken with reagent (2)	Appearance of a brown benzene layer	Formation of copper dithiocarbamates	0.2–10
Aromatic amines	(2) 1:3 mixture carbon disulfide and benzene Furfural in glacial acetic acid	Test solution treated on a spot plate with reagent	Violet color	Schiff base formation	0.1–200

*Continued*

**Table 3** Continued

<i>Functional group</i>	<i>Reagent</i>	<i>Procedure</i>	<i>Visible change</i>	<i>Remarks</i>	<i>Identification limit (<math>\mu\text{g}</math>)</i>
Nitro compounds	5% Benzene solution of tetrabase	Ether or benzene solution of sample treated with reagent and dipped into boiling water	Appearance of a yellow melt	Formation of molecular complex	0.1–50
Primary aliphatic nitro compounds	(1) Freshly prepared alcohol solution of Fast Blue B	On filter paper spot reagent (1), the alcoholic test solution and reagent (2)	Orange–red spot	Condensation product formation	0.5
Nitro compounds (aliphatic and aromatic)	(2) $0.5 \text{ mol l}^{-1}$ sodium hydroxide (1) Zn dust and acetic acid	Sample reduced with reagent (1) to the hydroxylamine. Add reagents (2) and (3)	Pink or violet color	Color more stable at $0^\circ\text{C}$ ; hydroxylamine interferes	
Aromatic nitro compounds	(2) Benzenediazonium chloride (3) Saturated diphenylamine in acetic (1) 10% aqueous calcium chloride solution	Few milligrams of sample dissolved in 3 ml of hot ethanol treated with reagent (1). Reagent (2) is added and the tube is heated to strong boiling. Cooled filtrate treated with reagent (3)	Purple, blue, or green color	Chloromycetin can be detected likewise	0.3–15
<i>m</i> -Dinitro aromatic compounds	(2) Zinc dust (3) 1% aqueous $\text{Na}_3[\text{Fe}(\text{CN})_5\text{NH}_3]$ (1) Amberlite IRA-400 resin beads (Cl-form)	On a white spot plate sample added to a few beads of reagent (1) followed by reagents (2) and (3)	Blue–violet color	Specific for dinitro aromatic compounds	$10^{-4}$ – $1.6 \times 10^{-3}$
Amino acids	(2) Saturated aqueous sodium sulfite (3) Dimethyl sulfoxide (1) 0.01% Fluorescein isothiocyanate in $0.1 \text{ mol l}^{-1}$ sodium hydroxide	On a TLC plate dried sample sprayed with reagent (1), heated at $90^\circ\text{C}$ for 10 min, cooled and sprayed with reagent (2). Heated again at $90^\circ\text{C}$ , before being observed under visible and UV radiation	Different colors for each acid	UV produces fluorescence	0.5–1.0 (visible light)
	(2) 0.25% ninhydrin in acetone				0.3–1.0 (UV)

Nitriles	(1) Oxalic acid	Sample and reagent (1) heated in a glycerol bath at 200°C for 5 min. After cooling, reagent (2) is added and the mixture heated to 140–160°C in a glycerol bath	Orange product	The tests may not be applied in the presence of ammonium salts, amides of acids, amino acids, and ureides	2–20
Aliphatic nitriles	(2) Thiobarbituric acid (1) 1:1 mixture of CaCO <sub>3</sub> –CaO	Solid sample mixed with reagent (1), heated in a glycerol bath at 250°C, with the mouth of the tube covered with a filter paper disk moistened with reagent (2)	Blue stain after 3–4 min		5–50
Thioketones and thiols	(2) 5% solution of Cu ethylacetoacetate and 5% tetrabase in chloroform Sodium azide in iodine solution	Test solution mixed with a drop of reagent	Evolution of bubbles of nitrogen	Catalytic reaction. Inorganic compounds containing sulfur(II) must be absent	$3 \times 10^{-4}$ –0.6
Primary and secondary thiols	(1) Conc. NH <sub>3</sub>	Test solution treated with reagent (1) in test tube, covered with reagent (2), and heated in a boiling water bath	Black stain (PbS) with a metallic luster	Tertiary thiols and thioketones give a negative response	1–100
Sulfonic acids	(2) Lead acetate paper (1) Succinic or phthalic acid	Solid sample mixed with reagent (1), heated in a test tube in a glycerol bath at 200°C. A disk of filter paper moistened with reagent (2) is placed over the mouth of the tube and the temperature raised to 250°C	A blue stain appears	Sulfurous acid is formed during the pyrohydrolytic process	1–20
Organic cyanates	(2) Iron(III) hexacyanoferrate(III) solution Dimethylbarbituric acid in aqueous pyridine	Test solution mixed with a drop of the reagent	Blue spot appears within 5 min		36–180 (μmol)

TLC, thin-layer chromatography.

**Table 4** Detection of individual compounds

<i>Compound</i>	<i>Reagent</i>	<i>Procedure</i>	<i>Visible change</i>	<i>Remarks</i>	<i>Identification limit (μg)</i>
Acetone	(1) Ethanolic solution of salicylaldehyde	Mix reagents (1) and (2) with the sample. Heat for 2–3 min at 70–80°C	Deep red color	Specific test	0.2
Acetic acid	(2) 40% aqueous sodium hydroxide (1) 5% aqueous lanthanum nitrate solution (2) 1 mol l <sup>-1</sup> ammonia	On a spot plate mix the sample with reagents (1) and (2)	Blue to brown rings within a few minutes	Sulfate and phosphate interfere	50
Acetylene	(1) Ammoniacal silver chromate	In a small porcelain crucible mix reagents (1) and (2) and sample. Stir for 10 min	Red–brown residue	Protective layer formation by acetylene	1
Barbituric acid	(2) 6 mol l <sup>-1</sup> acetic acid (1) 2 mol l <sup>-1</sup> acetic acid	On a spot plate mix sample with reagents (1) and (2)	Red–violet color	Formation of a violuric acid	10
Carbon disulfide	(2) Saturated sodium nitrite solution Copper sulfate solution treated with conc. ammonia and piperidine	In test tube treat sample with reagent and extract with benzene	A yellow–brown extract	Formation of copper dithiocarbamate	3
Carbon tetrachloride	(1) Quartz dust	In a test tube mix test solution with reagent (1). Immerse in glycerol bath at 150°C; cover mouth of tube with a disk of reagent (2), moistened with reagent (3)	Formation of a blue stain	Chlorine release in the presence of quartz	5
Citric acid	(2) Congo-red paper (3) 5% hydrogen peroxide (1) Potassium permanganate solution	In a test tube mix test solution with reagents (1) and (2). Warm slightly and after cooling add solid reagent (3)	White ppt forms	Pentabromoacetone formation	6
Cysteine	(2) Saturated bromine water (3) Sulfosalicylic acid (1) Aqueous sodium nitroprusside (2) 1% aqueous potassium carbonate	On a spot plate a drop of the test solution is mixed with reagents (1) and (2)	Pink to deep red color		0.001
Ethanol	(1) Potassium permanganate solution in (1:1) sulfuric acid  (2) Aqueous morpholine and sodium nitroprusside	In a test tube treat test solution with reagent (1), with mouth of tube covered with paper moistened with reagent (2)	Blue stain on the paper	Acetaldehyde formation	3

Formaldehyde	0.1% of J-acid (6-amino-1-naphthol-3-sulfonic acid) in conc. sulfuric acid	On a glass fiber filter paper add aqueous test solution to the reagent	After 5–10 s a yellow fluorescence under UV. The yellow solution turns blue after addition of water	Xanthylum dyestuff production	0.01
2-Furaldehyde	(1) Ethanolic aniline	Sample treated with reagents (1) and (2)	Brilliant red color		20
Formic acid	(2) Aqueous acetic acid (1) <i>N</i> -methylquinaldinium toluene- <i>p</i> -sulfonate in dimethyl sulfoxide	In a test tube treat sample with reagent (1) followed by reagents (2) and (3). Heat in boiling water for 1 min	Blue to green color	Cyanine dyestuff formation	0.004
Glycerol	(2) Pyridine (3) Acetic anhydride (1) Aminophenol in ethanol	In a test tube evaporate reagent (1) at 110°C, add the sample followed by reagent (2). Heat at 140°C for ~15 min, cool and add reagents (3), (4), and (5); cool	Bluish-green fluorescence under UV radiation	Formation of 8-quinolinol and its fluorescent sail	0.5
Hydrazine derivatives	(2) 1% arsenic acid in conc. sulfuric acid (3) Conc. sodium hydroxide (4) Magnesium sulfate solution (5) Conc. ammonia (1) Dowex HCR resin (H <sup>+</sup> form)	In a test tube mix 5 beads of reagent (1) with test solution and reagent (2). Heat in a boiling water bath for 15 min. Place beads on a spot plate and mix with reagent (3)	Hydrazine, alkyl and arylhydrazines give orange–red bead surface		
Malonic acid	(2) 2% Dimethylaminobenzaldehyde in acidified ethanol (3) Aqueous 2.5% ammonia (1) Urea in methanol	In a test tube mix test solution with reagent (1). After evaporation heat tube for several min in a glycerol bath at 120°C. Add a drop of reagent (2) and heat for several minutes	Reddish-blue color which fluoresces red under UV radiation	Conversion into barbituric acid	50
Nitrobenzene	(2) Pyridylpyridinium dichloride in dimethylformamide (1) Zinc dust in slightly acidic medium  (2) Alkaline phenol solution	In a microcrucible treat test solution with reagent (1) to reduce analyte to phenylhydroxylamine, which rearranges with acid to 2- and 4-aminophenol. Add reagent (2) to form indophenol blue	Deep-blue color		0.01

Continued

**Table 4** Continued

<i>Compound</i>	<i>Reagent</i>	<i>Procedure</i>	<i>Visible change</i>	<i>Remarks</i>	<i>Identification limit (μg)</i>
Oxalic acid	Solid diphenylamine	In a test tube evaporate sample to dryness and melt with reagent over a flame. After cooling add ethanol	Blue color	Aniline blue formation	5
Phenylhydrazine	Cacotheline in sodium hydroxide solution	Treat test solution with reagent on a spot plate	Blue product		0.02
Piperidine	(1) Solid sodium carbonate	In a test tube mix acidic test solution with reagent (1). Immerse in water bath at 90°C and cover the mouth of the tube with a disk of filter paper moistened with reagent (2)	Red spot on yellow paper		20
Pyridine	(2) Aqueous sodium 1,2-naphthoquinone-4-sulfate Trisodium pentacyanoaminoferrate(III) in pH 6.5 buffer	Place sample on filter paper and spray with reagent	Yellow–orange color within 5 min	Replacement of the ammonia with pyridine in the coordination sphere of iron(III)	10–50
Salicylaldehyde	70% perchloric acid	Introduce the anhydrous test solution into a capillary tube, and dip into the reagent	A yellow color appears which turns red when standing in the meniscus	Protonation of the carbonyl oxygen	2
Urea	(1) Urease  (2) Nessler solution	On a spot plate treat the neutral or alkaline test solution with reagent (1) and after 2–3 min with reagent (2)	Brownish ppt	Enzymatic hydrolysis of urea	1

while in the second stage hydrogen peroxide/peroxidase oxidizes *o*-tolidine to a blue quinoidal product.

In another dry-reagent configuration in Diasti<sup>®</sup> (Ames Co.) the *o*-tolidine in the second stage of the reaction is replaced by potassium iodide, which is oxidized in the presence of peroxidase to form free iodine. Newer test strips contain hexokinase in place of glucose oxidase. A very sensitive spot test for Benedict-positive compounds is described, which uses 2,2'-bichinchoninate as a chromogen. This test is ~10 000 times more sensitive than the classical Benedict test.

Several companies are now offering plastic strips with eight or nine separate reagent areas affixed that fulfill in only 1 min the function of a routine urine analysis laboratory. These include N-Multistix<sup>®</sup> and Hema-Combistix<sup>®</sup> (Ames Co.), the Combur-9-Test, BMD Chemstrips, and BM 33071 glucose pad (Boehringer Mannheim), and the Rapignost (Hoechst AG).

To eliminate interpersonnel variations in interpretation of the dipstick colors, simple reflectance scanning instruments may be used. The Ames Clinitek Auto 200<sup>®</sup>, Glucometer II, and Seralyzer, the Urotron L R System, Reflotron, Rapignost Total Screen L, Reflolux II and Accu-Check II (Boehringer Mannheim), the Glucoscan 3000 (Lifescan, Inc., Mountain View, CA), the Super Action Analyzer SA 4220 (Kyoto Daiichi, Kogaku), the Cobas Bio Analyzer (BCL, Lewes, UK), the Y Si 23 A analyzer (Clandon Scientific, Aldershot, UK), and the Cheme-Trics Analyzer (Technicon, Tarrytown, NY) are all reflectance measuring instruments that irradiate the dipstick with polychromatic light and measure the reflected radiation.

### Protein in Urine

Next to glucose tests, protein tests are the most frequently performed tests in routine urine analysis.

The first spot test configuration for urinary protein was based on deproteinization and turbidimetric estimation of the coagulated protein. The BUM-INTFST<sup>®</sup> tablet (Ames Co.) contained a premeasured amount of sulfosalicylic acid; the amount of protein was visually estimated by the degree of turbidity of the solution in the MICROBUM-INTFST<sup>®</sup> (Ames Co.). There was no correlation what so ever with urinary pH.

The most important spot test for native albumin, widely applied today by manufacturers of diagnostic products, is based on 'the protein error'. Proteins and their decomposition products often interfere with colorimetric pH determination. The analytical use of

anomalies in color reactions carried out in the presence of protective colors was demonstrated by Feigl and Anger, but was only utilized by a commercial company 20 years later in a system applying dry-reagent technology (Albustix<sup>®</sup>, Ames Co.). This test exploits the fact that the blue aqueous solution of the potassium salt of tetrabromophenolphthalein ethyl ester becomes yellow on addition of dilute acetic acid. The blue can be restored by adding alkali. If, however, a solution or suspension of native albumin is added to a dilute blue solution, a great deal of acetic acid can be introduced without causing the blue to change to yellow.

### Bilirubin in Urine

There is a need for a simple, sensitive, and reliable bilirubin test that can be used routinely by the physician for the detection of bile in urine.

Barium chloride-impregnated dry paper strips are dipped in urine samples for 30–120 s and then spotted with two drops of Fouchet's reagent (10% FeCl<sub>3</sub>, 25% trichloroacetic acid in water). A positive test is indicated by the appearance of a green color.

### Nitrite in Urine

Testing of urine for nitrite is important because it can be used to detect urinary tract infection. The basis of the spot test used in the Nitur-Test<sup>®</sup> (Boehringer Mannheim) and in the Rapignost<sup>®</sup> strip system (Hoechst AG) is the classical Griess test.

In the strip formulation of the Nitur-Test<sup>®</sup> sulfanilamide reacts with nitrite in an acidic buffer medium to form a diazonium salt, which couples with 3-hydroxy-1,2,3,4-tetrahydrobenzoquinoline to give a red azo dye.

The nitrite test of the Merck Co. detects as little as 10 µg l<sup>-1</sup> nitrite. It uses filter paper impregnated with an aqueous solution containing methanol, 1–2 g of a diazotizable amine, 0.1–0.5 g of a coupling component, and 2–8 g of solid organic acid per 100 ml. The paper is dried and cut into strips and is specific for nitrite independent of urinary pH. The test reveals significant bacteriuria when the bacterial count reaches 1 × 10<sup>7</sup> ml<sup>-1</sup> of urine.

### Ethanol in Urine

The synergistic action of ethanol with other drugs makes the detection of alcohol important and urgent.

Alcoscan test strips contain alcohol oxidase and horseradish peroxidase with colorimetric reagents (3-methylbenzothiazolinone hydrazone hydrochloride and 3-dimethylaminobenzoic acid).

A 1–5 ml urine sample is placed in a 15 ml centrifuge tube and the test strip is suspended in the air

space above the sample. The stoppered tube is heated at 65°C for 5 min and the color development estimated from a color chart.

### Detection of Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common of the genetic diseases that lead to early death. One of the classical clinical indications for the diagnosis of CF is an abnormally high concentration of sweat electrolytes.

An indicator system for CF consists of three filter paper strips impregnated with 0.1 mol l<sup>-1</sup> potassium dichromate. These are soaked in 0.05, 0.066, and 0.1 mol l<sup>-1</sup> silver nitrate solutions, respectively. The strips are covered with waxed paper for protection. The indicator system is attached to a suitable part of the body of the child for 15 min. The indicator strips are removed and read. A positive result is signaled by the decoloration of the originally red-brown papers. If none or only one indicator strip shows a positive reaction, the sweat chloride concentration is  $\leq 35$  mmol l<sup>-1</sup> and the child is considered normal. Children showing chloride concentrations of 35–55 mmol l<sup>-1</sup> (two of three strips reacting positively) need to be checked more thoroughly. Concentrations of  $> 55$  mmol l<sup>-1</sup> chloride (all three indicators reacting positively) indicate a high probability of CF.

## Forensic Applications

Of the objective physical evidence that a forensic scientist collects, a considerable amount is based on simple spot tests.

In homicides committed with a gun it is important to find out the shooting range. A great deal of corroborative evidence can be collected by detecting red blood cells and spermatozoa at the scene of a crime. The search for illicit drugs is greatly facilitated by selective spot tests in their preliminary identification.

### Firearm Discharge Residues

Reliable and sensitive methods for demonstrating the presence of residues of firearm discharge on the clothing of a victim or on the skin of a suspect are sometimes qualitative tests. The detection of nitrate and nitrite in such residues can be achieved by spot tests. The detection of traces of antimony and barium, which are present in many cartridge priming charges, on the web of the thumb and back of the hand, can supply data relevant to the question of whether a head wound, resulting from being shot with a revolver, was self-inflicted. The relatively recent discharge of a firearm is indicated by the detection of the most frequently encountered metallic components of firearm discharge residues, such as lead, copper, nickel, barium, and antimony.

The classical Griess reaction and its numerous modifications is a specific nitrite test, but the common obstacle faced by criminologists is the presence of blood. The color of the blood and that of the red azo dye produced by the Griess reaction are similar. Detecting nitrite by fluorescence under UV radiation solves this problem. Whatman No. 1 filter paper is soaked in a freshly prepared 5% solution of *o*-phenylenediamine dihydrochloride and partially dried. This filter paper is placed over the suspected area of the gunshot on the clothing, exerting slight pressure for better contact with all parts of the clothing. The paper is removed and placed in a Petri dish containing a 25% ammonia solution. The paper is illuminated with 254 nm UV radiation. The yellow fluorescence pattern may be photographed as permanent evidence.

### Simple Drug Tests

As the problem of drug abuse reaches epidemic proportions, the use of simple tests gains considerable importance. In recent years, various instrumental methods for identifying drugs by their physical properties have been greatly improved. These are enormously useful, but are outside the scope of this article; we are only concerned here with quick chemical methods feasible for field conditions. Some representative examples of such tests are presented below.

**Opiates** Several drops of Marquis reagent (8–10 drops of 40% formaldehyde in 10 ml of concentrated sulfuric acid) are added to 1–2 mg of drug. The presence of opiates is indicated by the appearance of an intense purple turning to blue-violet.

A simple and effective separation of opiates may be achieved by thin-layer chromatography (TLC). On silica gel 60 GF plates, CHCl<sub>3</sub>-hexane-triethylamine (9:9:4; v/v) is applied as the mobile phase.

Illicit heroin (diamorphine) may be screened by dissolving the sample in methanol and applying this to silica gel 60 GT 254 plates. The chromatograms are developed with toluene-acetone-ethanol-diethylamine (30:60:7:3; v/v) and the spots are visualized by UV irradiation at 366 nm.

**Detection of barbiturates in urine** A few drops of Zwikker A (1% cobalt(II) acetate solution) are added to a few milligrams of drug, followed by a few drops of Zwikker H solution (5% isopropylamine in methanol). The presence of barbiturates is indicated by the appearance of a blue-violet color. Blood and urine samples are analyzed by TLC on silica gel G with CHCl<sub>3</sub>-acetone (17:3; v/v) as mobile phase.

Visualization is effected by spraying with diphenylcarbazone– $\text{HgCl}_2$  reagent followed by methanolic 1% KOH.

Components in drug mixtures may be simply identified by dissolving the sample in 2 ml of ethanol, filtering, evaporating the filtrate to 0.5 ml, and applying 5  $\mu\text{l}$  portions to a silica gel–gypsum layer for development with ethyl acetate–ethanol–aq. 25%  $\text{NH}_3$  (18:2:1; v/v). Iodine vapor is used to detect phenobarbitone, bromvaletone, papaverine hydrochloride, and caffeine.

**Screening for LSD** Ehrlich's reagent produces a characteristic purple to deep-blue color with lysergic acid diethylamide (LSD).

**Screening for amphetamines** A highly sensitive screening strip for methyl amphetamine in urine may be prepared using the Simon reagent. A silica gel TLC plate is sprayed with equal volumes of 2% sodium nitroprusside and 5% aqueous sodium carbonate solution, and dried for 3 h at  $110^\circ\text{C}$ . A strip is cut from the plate to use in the test.

Urine (alkaline, 5 ml) is extracted with 2 ml of benzene and a 20  $\mu\text{l}$  portion of the benzene layer is spotted onto the strip, which is then exposed to acetaldehyde vapor; a blue color indicates the presence of  $>0.1\text{ }\mu\text{g}$  of methylamphetamine.

The same Simon reaction may be used for rapid screening of methylamphetamine in urine in a Sep-Pak  $\text{C}_{18}$  cartridge.

**Screening for marijuana** The most widely used illegal drug is marijuana, which consists of dried parts of the *Cannabis sativa* plant. Its concentrated, more potent, form is hashish, the resin form of drug which contains  $\sim 30$  derivatives.

In the optimized rapid method 5 mg of hashish or 50 mg of marijuana is extracted with light petroleum–diethyl ether (4:1; v/v). The extract is evaporated to dryness, the residue dissolved in 0.5 ml of 1% 4-dimethyl-aminobenzaldehyde in concentrated  $\text{H}_2\text{SO}_4$  and the solution is heated for 3 min in a water bath. A purple–red color is produced immediately, turning to indigo blue on pouring the mixture into cold water. This dual color reaction is specific for extracts of hashish and marijuana and can be used to distinguish them from other plant extracts.

**Screening for salicylates** Overdoses of aspirin and other mild analgesics are extremely common. Salicylate is commonly detected in urine by the classical violet iron(III)–salicylate chelate formation.

The same simple test is used for the detection of salicylate in hemolysed whole blood; 0.3 ml of blood

is mixed with 0.6 ml of methanol and the mixture is centrifuged at 3000 rpm for 5 min. The supernatant solution is filtered and 50  $\mu\text{l}$  of 0.5% iron(III) chloride solution is added to 0.2 ml of the filtrate. A violet color at the diffuse interface indicates the presence of salicylate.

**Screening for blood** Chemical testing for blood or traces of blood is often needed to provide physical evidence in cases in which direct visual inspection is not a decisive proof.

Blood is identified in most cases on the basis of the peroxidase-like activity of the heme group of hemoglobin. In the classical blood test, benzidine is oxidized to the quinoidal benzidine blue by hydrogen peroxide in the presence of hemoglobin. Since benzidine and its salts are now considered to be carcinogenic, 3,5,3',5'-tetranethylbenzidine is used instead.

**Screening for semen** The high incidence of sex crimes necessitates the rapid identification of semen. The male germ cells contain acriflavine, the presence of which has direct diagnostic value.

At high dilutions acriflavine fluoresces under UV radiation; this offers the basis of a very simple test for semen. Unfortunately, modern laundry brighteners also fluoresce very intensely.

Semen is generally detected by identifying acid phosphatase or choline. The suspected stain is cut and incubated for 30 min at  $37^\circ\text{C}$  with two drops of a 0.1% aqueous solution of disodium phenylphosphate; the phenol resulting from the enzyme-catalyzed hydrolysis can be detected with the Folin–Ciocalteu reagent. Phenol forms molybdenum blue on reaction with the molybdophosphate or tungstophosphate incorporated in this reagent.

Choline can be identified by a microscopic crystal test. The aqueous extract is treated with the Florence iodine reagent (6.6 g potassium iodide and 10.6 iodine dissolved in 120 ml distilled water). Characteristic rhombic crystals are observed.

## Water Quality Screening

In 1974, the Safe Drinking Water Act was passed by the US Congress and the Environmental Protection Agency (EPA) took responsibility for ensuring the safety of water supplies. The EPA proposed a list of materials that carry potential hazards when present in drinking water. Maximum allowable levels were set for more than a dozen inorganic species (As, Ba, B, Cd, Cr(VI), Cu,  $\text{CN}^-$ ,  $\text{F}^-$ , Pb,  $\text{NO}_3^-$ ,  $\text{NO}_2$ , Se, Ag) and for about the same number of organic pesticides. Turbidity and the amount of coli-form bacteria were also limited. Additionally, secondary

regulations were issued in 1977 dealing with the esthetic qualities of water. These are connected with the sulfate, iron, and manganese contents of drinking water.

Spot tests based on simple kits for quick and inexpensive water testing still find wide application and a number of commercial companies market variations of the test kit methods that are approved by the EPA for Safe Drinking Water Act reporting and recommended for onsite testing.

The reliabilities of spot test-based water analysis kits for ecological purposes have been evaluated. Statistical analysis of the results for a large series of samples showed that for routine purposes there was good agreement ( $r > 0.85$ ) with the results of standard methods. When high accuracy and precision were needed, however, the kits were unsuitable.

## Basic Principles

In analytical chemistry, many problems require completely different approaches or different type of automated computer methods in order to arrive at the desired solutions. One very important step is separation or isolation of the compound; however, we will begin from the stage in which a compound is available in a pure form. The problem we shall focus on in this article is structure elucidation based on different spectroscopic methods.

The problem of structure elucidation has a very broad range of goals: from the identification of only few constituent structural fragments of the unknown compound to the complete three-dimensional structure determination. The problem of establishing reliable correlations between different types of spectra (infrared (IR), ultraviolet, mass,  $^1\text{H}$  nuclear magnetic resonance (NMR),  $^{13}\text{C}$  NMR, etc.) and the chemical structure (or structural fragments) are diverse and have not yet been completely solved. In order to shed light on the prospects for solving this problem, some of the main difficulties and encouraging developments are summarized below.

The main difficulties are:

- The number of registered chemicals is over 20 million (Tuesday, March 4, 2003, at 05:34:17 there were 21 108 454 organic and inorganic substances registered; Monday, April 14, 2003, at 10:51:24 the number increased to 21 287 895). Approximately

4000 new substances are added each day to CAS Registry. Spectral data exist for only a minor portion of these compounds; the computer-readable formats, if available, are not standardized and thus difficult to exploit.

- The spectra held in collections may contain significant experimental errors, which are dependent upon the laboratory, spectrometer, source of material, sampling, experimental conditions, purpose of the measurement, and the operator.
- The number of theoretically possible structures even for a modest set of fragments may be prohibitively large. Extremely fast growth of the number of possible structures with an increasing number of fragments, called combinatorial explosion, virtually precludes their exhaustive generation and back-checking with spectral simulation.
- The logical rules for linking spectral features with the structural ones and vice versa are so diverse (dependent on very large structural or spectral parts) and so numerous that the decision between ‘encoding all, even minute rules’ and ‘encoding general rules and all exceptions from these rules’ has to be made. Since many rules or correlations are not even known it is practically impossible to collect them all.
- The level of cooperation between the human experts from different fields (chemists, spectroscopists, programmers, artificial intelligence researchers, psychologists, etc.) required to build a good chemistry-oriented expert system is in most cases far too low.

The list of problems could be even longer, but there are some encouraging developments that may aid the solution of spectra–structure correlation problems that should be mentioned as well. In some areas the

successes have been remarkable. Among the most encouraging factors are the following:

- Small changes in spectral (structural) features have been shown to be caused by small changes in the solutions sought, i.e., the structures (spectra). Such analogies can be widely used.
- Computer methods for the reduction of measurement spaces, such as fast Fourier and fast Hadamard transforms, principal component analysis, autocorrelation, genetic algorithm, and others, can be applied successfully.
- A number of software packages for accomplishing specific tasks (generators of all isomers, interactive structure editors, various spectra simulation programs, etc.) are available. Different input and output formats of spectral and structural data are often an optional choice. Besides, many databases are available online through the internet for browsing structural and spectral data.
- A number of heuristic rules linking structural fragments with parts of spectra and vice versa are known.
- In the laboratories performing routine analysis (analytical work, quality control, violation of regulations control, etc.) there is a considerable interest for automating the routine part of the work.
- A rapid increase in computational power accompanied by the lower price of hardware and more powerful software available on the market has aroused interest in using calculation-intensive methods for everyday applications.

The factors listed above are mostly unrelated and may not be pertinent to the solution of every problem of this kind. A thorough study of the suitable methods for learning, data reduction, feature extraction, or decision-making processes has to be made separately for each problem.

In general, methods of solving the spectra–structure correlation problems are based on three different approaches: on library searches, on expert systems, and on various modeling techniques.

Library searching techniques are of two kinds: identity searches and similarity searches. Identity searches (i.e., searches requiring an exact match between the query and the reference) are successful only if the sought spectrum or structures are ‘already’ in the reference library. If not, the search fails completely. In contrast, similarity searches depend on the metrics introduced into the representation of the spectra or structures. The metrics and consequently the distance or the similarity measure between the query object and the reference depend on the problem being studied; hence, the results obtained on the basis of similarity are not directly comparable when the problems are from different fields.

Another approach to solving structure elucidation problems is to use the ‘strategy’ of the expert system. This strategy consists of the logic rules-driven process that combines a broader knowledge base (including the logic rules) with the methods and procedures required to make partial or final conclusions. With this combination, systems capable of complex decisions in the structure elucidation process can be created. The best spectroscopic applications on expert systems are in the fields where the problems are well defined (large number of structure–spectra relationship logical statements) and the methods or procedures as to how to move from the description of the problem to the desired solution are established and formalized (hierarchy of rules and/or forward and backward chaining of questions and answers, etc.).

The third possible approach to the structure elucidation processes is to find procedures, the so-called modeling techniques, which are capable of making hypotheses on basis of which problem can be solved. For example, a set of procedures should be able to predict from spectral data all structural fragments, from which a structure generator could yield all possible structures. The resulting structures are then ranked and evaluated. In structure elucidation systems based on modeling techniques, the search procedures are only partially built on rules or other information provided in advance in a knowledge base. The solutions are learned from real examples rather than by using fixed rules. Such learning procedures are known as self-learning methods.

In practice, structure elucidation processes are very complex and for determining different specific structural features any of the three mentioned approaches can be used. It is possible to integrate the library searches and/or various modeling techniques into expert systems, or vice versa.

## **Use of Databases or Library Systems**

The success of a library search in analytical chemistry depends very much on the data representation. Different kinds of data (numerical, textual, spectral, structural) require appropriate treatments. Usually, spectral data collected from the instruments are not in a form suitable for direct input either into a collection or as a query for a library search. Once the spectrum is in the computer, a number of preprocessing steps (e.g., smoothing, baseline correction, normalization, peak and intensity detection, reduction of the measurement space, autocorrelation, deconvolution, shape tracing, etc.) should be applied in order to bring the data into a standardized format

and to extract the key features. The preprocessing steps must be applied selectively, bearing in mind that too extensive a use of preprocessing methods may cause a considerable loss of valuable information, thus jeopardizing the possibility of reaching a final successful solution. On the other hand, when starting to build a database of high quality, as many preprocessing methods as possible should be implemented to make the handling of the databases flexible and the system versatile.

The structure of the chemical compounds under investigation influences all aspect of its chemistry, particularly spectroscopy. Therefore, the handling of chemical structures is one of the basic features that have to accompany the library search. For the input of chemical structures into a computer, flexible on-line editing of chemical graphics is required.

All input spectra and structures must also be saved in direct access files for later use in the iterative process or for checking the results. Different data types (structures, spectra, sets of commands) must be coded uniformly in all system modules for input and output. The same is true for the files on which the final or intermediate results are stored. Because a resulting output file of one module may act as an input file to another one, or be used as an input for starting a new problem, all data exchange processes and files must be standardized. Good library search systems perform the reformatting of data transparently to the user.

Other types of possible input such as numbers and textual requirements that serve as supplemental information to the basic data are handled by special-purpose decoders that, unfortunately, are almost always custom designed.

Library systems designed to retrieve references identical to the query are called identity search systems. Since the identity of any object (spectrum, chromatogram, chemical structure, set of chemical features) is well defined, the identity search is reduced to the binary decision identical/not identical. The system has to be insensitive to varying instrumental conditions, but there is no need to discriminate between different degrees of similarity. The identity search system is useful only in a limited range of applications; for example, in the field of environmental control or drug control where the set of compounds that are expected or have to be identified are exactly specified. Any other, unspecified compound is irrelevant. In most other applications the unexpected compounds are of prime interest, so that the identity search is of limited use.

For the research and development purposes where the emphasis is on new compounds not yet contained in the libraries, similarity search systems able to

retrieve compounds similar to the unknown have been developed. The measure of similarity is related to the distance between two objects, and therefore depends on the object's representation, on the choice of metrics for the measurement space, and, consequently, on the choice of a mathematical expression for the distance calculation. If the similarity search is applied to spectra, it is not too difficult to calculate the similarity. The similarity search becomes more complex when the queries are chemical structures. At present, there is no generally accepted unique similarity measure for chemical structures. Different spectroscopic methods focus on different structural entities and so are concerned with different aspects of structural similarity.

Because identity is the upper limit of similarity, similarity search systems may always be used for identity searches. However, when used as an identity search, similarity search systems are not very efficient because the requirements for checking the similarity introduce lengthy algorithms to the system, which may use conflicting criteria and thus resulting in compromise. In order to distinguish identical compounds from not-identical ones, in a similarity search, the degree of similarity has to be defined in such a way as to give a significant difference between compounds with slightly different chemical structures, and a small difference between samples of identical chemical structures. On the other hand, the system should be tolerant of slight impurities in the sample of the unknown. It is very important to consider in a search system: (1) the selection of spectral features that are structure sensitive, and (2) how to normalize and scale the similarity measure. In order to make the correct choices, knowledge and experience in the particular spectroscopy are required.

## Expert Systems

### General

Expert systems are expected to solve problems always in close 'collaboration' with the user and not entirely by themselves. Dialog between the user and the system can lead to much better performance than if the systems were left by itself to work on the problem automatically. Expert systems help the user to solve problems; the more extensive and complex the help, the better the expert system.

There are many different opinions as to when a set of programs and data can be considered to be an expert system. A computer scientist working on the development of an expert system would favor the following definition:

Expert system = Knowledge base + Inference engine

where the inference engine interprets and exploits the knowledge base, which can be in many different forms (rules, frames, logic rules, tables, formulas, etc.). The 'inference engine' is usually separated from the knowledge base in such a way that the knowledge base can easily be changed without changing anything in the inference engine.

In the language of artificial intelligence, the expert system is able to recognize each possible situation (state) in the problem space and respond with an appropriate action, which will lead closer to the final solution. For example, on the basis of spectral features the system must be able to select possible structural fragments. One possibility is that the rules for the spectra-structure correlations are built into the inference engine by an expert. Another possibility is that the modules for clustering the spectra from available spectral collections provide automatic decisions about some spectra-structure correlations. Spectra in the same cluster have common spectral features. These features must be assigned to structural fragments common to all compounds having spectra from the cluster investigated.

It should be emphasized that expert systems are not expected to make fundamentally new discoveries; it is enough if they are able to identify situations, partial solutions, or ways toward a solution that were not known before, or at least that the system designers had not thought of in advance. It is very important that the expert system informs the user about the new situation when it is discovered, and demands from the user the explanation and instructions as to how to react or what to do in the particular case and in similar cases in the future.

The main components that must be known, accessible, or computable during the planning, developing, and testing an expert system are as follows:

- description (explicit or implicit) of possible states that can appear in the problem space;
- description (explicit or implicit) of possible solution states;
- means for the recognition of states;
- criteria for the evaluation of states;
- answers (reactions, ways) leading from the problem toward the solution;
- criteria for the evaluation of answers;
- means for the selection of the best possible answer (way); and
- means for the construction of new or intermediate states in the problem space.

Some of the above components might be omitted and others added. The description of states and different criteria for evaluations can be regarded

as a knowledge base, while the recognition of states, generation of answers, and the selection of the best answers can be regarded as parts of the inference engine. However, it is often hard to draw a clear line between both components.

The main guideline along which the expert systems work can already be recognized from the above components, which, of course, can be (and most often are) performed in an iterative way. From the initial state of the problem, the expert system must come to the final state (the solution) via a number of intermediate steps.

### **Acquiring the Knowledge**

Knowledge is the most important part of any expert system. The simplest way of implementing the knowledge is to transfer it to the expert system in one of the following forms:

- known facts (constants);
- mathematical formulas;
- tables or collections of data;
- description of representatives (frames);
- procedures (algorithms);
- logic rules (if 'condition' then 'action'); and
- heuristic rules.

For the designers of expert systems the logic and heuristic rules are regarded as the most interesting. Because branching is a fundamental property of logic rules, a collection of rules becomes very hard to follow, maintain, correct, and change when the number of rules increases. Additionally, if the solutions of the real-world problems are to be described with a tree of logic rules, the numbers of rules and exceptions to them (which are also described and resolved as logic rules) may become so immense as to become out of control. To avoid this problem, heuristic (experience based) rules and fuzzy rules are introduced. The difficulty initiated by the use of heuristic and fuzzy rules is not in their formulation, nor that they would not hold for certain, but in the fact that in most cases even the percentage of the confidence limits is not exactly known. In the fuzzy logic approach mathematical 'probability' is not appropriate and is replaced with an alternative theory called 'possibility' theory. The idea behind fuzzy systems is that values for 'truth' and 'false' are not only 1 and 0, respectively, but any value between 1 and 0. Fuzzy 'truth' values deal with the 'likelihood' or 'probability' that a fact or rule is true.

To handle large numbers of logic, heuristic, and fuzzy rules, a variety of supporting software (expert systems shells, languages specially designed to handle logic, etc.) has been developed and is now available

'off the shelf'. But in spite of all support offered, the basic scheme of rules must first be obtained from a human expert and then input by the designer into the expert system. Very often even the best human experts are not able to describe or clearly define the logic routes for solving a given problem. This obstacle in designing and programming of expert systems is called the 'Feigenbaum bottle-neck'.

Human experts can be aided and their work complemented by the use of self-adapting and self-learning procedures that can acquire knowledge by themselves. Two strategies have been developed for self-learning systems: supervised and unsupervised learning. If the system learns, i.e., acquires knowledge, with the aid of its tutor or by itself, the learning is called supervised or unsupervised, respectively. For both kinds of learning the selection of the database is very important. The designer of an expert system must use only collections of high quality to form the basis of self-learning procedures. It is also important to choose a qualified tutor, preferably a human expert in the field for which the computerized system is intended and not the designer of the expert system. The expert's task is to explain the meaning of the data which the computer system has selected from the partial solutions obtained at various stages (intermediate states) of the problem-solving process. The system first inspects the data, finds certain patterns, classes, clusters, or groups within them, and where it is not able to interpret the pattern, it requires the tutor's description of the meaning (or influence) of the patterns on the general solution. The tutor's answers are interpreted and connected to the already existing knowledge. In short, learning from examples rather than by following rules is favored in cases where the rules are difficult to write down explicitly.

### Neural Networks in Chemistry

The problem of establishing reliable correlations between different types of spectra (IR, mass,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, etc.) and the chemical structure or structural fragments of the corresponding compounds is so elaborate that a complex approach is needed. The neural network approach offers a valuable possibility to develop an automated system capable of dealing with such complex relations. The main effort of neural network research is training the network to obtain the model. After the model (neural network in our case) is obtained, it acts as a 'black-box' that provides reliable answers when a set of measured values (input variables) is fed into it. Although the training might be quite lengthy, the answer or prediction of a trained neural net is almost instantaneous,

especially if the net is implemented on a parallel computer. As a rule, the model is built on the available set of data such as a spectroscopic database, a set of historical recordings of process control, protein sequences, a set of multicomponent analyses, etc. Sets of data containing a number of interesting dependencies, feature correlations, and other information that cannot be deduced in a straightforward manner from first principles, by theoretical calculations, or even with numerical methods, are the best targets for neural network applications. Among all different types of neural networks, the feed-forward neural network based on the 'back-propagation of error' learning algorithm has been applied most frequently for structure-solving problems. The next very successful algorithm worth to be mentioned is self-organizing algorithm, originally used in Kohonen neural networks, which produces 2D self-organized maps (SOMs) of input objects. The information contained in 2D SOMs can be exploited for clustering, classification, variable selection, outlier detection, etc. The SOMs can be also employed into counter-propagation neural networks, which are based on initial self-organizing algorithm and extended by supervised learning algorithm yielding the response surface used for predictions.

### Communication between the User and the System

A vital part of the expert system that is too often neglected by the designers and by the researchers of the expert systems is the communication between the expert system and the user. Good communication provides the information about the point in the decision process from where a particular dialog starts; the user should understand the implications of his or her answers on the progression of the elucidation process and its final solution. To achieve this, the communication system must employ appropriate means such as menus, graphics, keyboard typing, pointing devices, help messages, links to other resources, and explanations. In a good expert system, the wording, the order, and the form of questions are adjusted to the level of a chemist, not to the level of a computer specialist. The online help must be available from all communication points of the system. Both general and context dependent help are better if supported with examples.

### Modeling Techniques for Special Methods and Procedures

#### General

The expert systems that are able to design and evaluate hypotheses can be regarded as models for solving

special problems. We shall focus here on spectroscopic systems with the limitation that they will be dealing with pure compounds only. The problem of mixtures (first qualitative identification of components and next quantitative determination of their amounts in the mixture) is far too complex to be solved for the general case. However, a well-designed spectroscopic expert system can offer a number of possibilities (structural features, combination of fragments, correlation of spectral parts with different types of compounds, etc.) if the spectra of a mixture are input.

A commonly used graphic presentation of such systems is a path of circular shape indicating a cyclic procedure of postulating and optimizing hypotheses. The process begins with the input of a spectrum of the unknown sample with all additional available data (known fragments, mass formula, constraints, chemical and physical constants) and finishes with the proposed structure and corresponding simulated spectrum (property). Between the input and output steps various intermediate procedures are necessary. The input data serve to predict one (or several) possible chemical structure(s) of the unknown sample. The simulation techniques are then applied to the proposed chemical structures and simulated spectra are compared with the original (input) spectrum. The predicted structure giving the simulated spectrum most similar to the original one is the most probable solution for the unknown structure. The whole procedure is shown in **Figure 1**.

This circularly designed system must allow the user to start his or her problem at different points of the solution-seeking process. The user is not always interested in the entire process. Often, the user has a partially solved problem and would like to know just a minor detail or alternative solution if it exists. Sometimes users have very simple problems such as searching a given spectrum, fragmentation of a structure, building a small database according to specific needs, or modifying the instrumental output (correcting baseline, removing noise, deleting part of the spectrum). Because the tools for solving minor problems are already available, each spectroscopic system should allow many different types of data as input and offer access to individual modules at user's will. In general, the solution-seeking process is two-directional, or, if looking from the algorithmic point of view, the process is cyclic and it allows the flow of data in both directions.

### **Input of Data**

The complex modularly built systems should be able to work with different types of data as well as with

the incomplete or corrupted data. The user may have only partial spectra or a few fragments. Handling different types of input must be designed carefully to enable the user to concentrate on the problem and not on data typing.

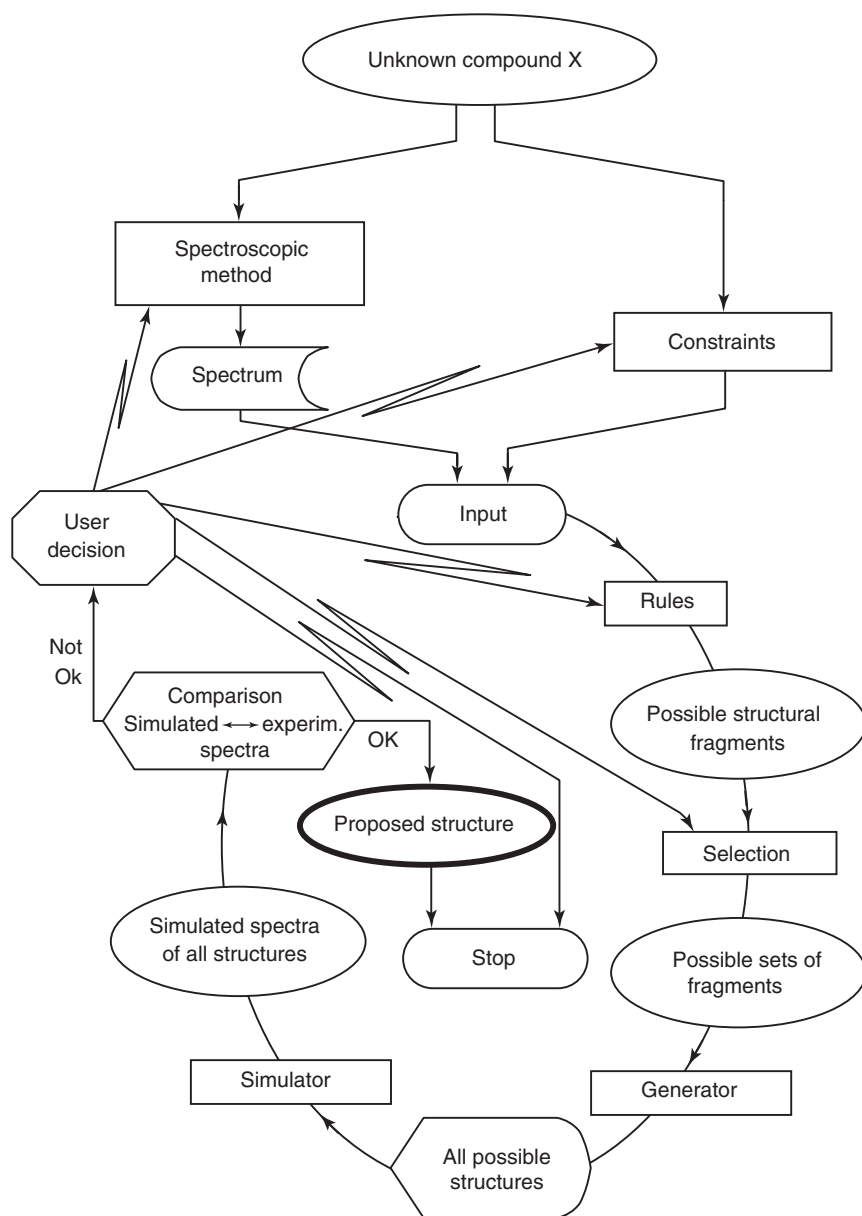

In both directions of the solution-seeking process (from the structure as input toward the spectrum, or vice versa) the system first transforms the input data into the representations it understands, i.e., the representations that enable the algorithms to be performed. The most standard spectral data are the peak positions, intensities, and shapes of the specific parts of the spectral curve, the area below the curves and the periodic patterns of peaks in the spectra. The main structural features are the spatial and topological relations of structural fragments with the aspect to the rest of the structure. Topological properties are deduced from connection tables, while spatial positions, orientations, and possible degrees of freedom of rotation or vibration of structural parts are usually obtained in an interactive online dialog with the user. However, the system must be able to detect the positions in a structure where certain spatial effects may occur and ask the user for detailed instructions if the questions cannot be resolved due to lack of data.

### **Building the Hypothesis**

Before the problem of structure elucidation can be completely solved, possible pieces of the unknown spectrum or structure must be obtained, from which a model for the solution can be constructed. Many different methods and processes are applied to obtain the building blocks of the solution. Among the most important ones are logical and heuristic rules of the type:

- If spectrum of type A contains feature B, then structural fragment C is present and D is absent.
- If structure A contains fragment B, then spectrum of type C will show feature D.

As was mentioned earlier, artificial intelligence methods such as pattern recognition, supervised and unsupervised learning, or neural networks can be successfully applied for building the hypothesis. The recognition of common patterns in spectra belonging to the same type of compounds and clustering of spectra in order to find common structural features are two main problems in the field. The key point is always the same: to correlate spectral features to the structure and then the structure to the sample's properties. At the hypothesis-building stage as much information as possible should be extracted from available data to achieve a good starting point. The

**Figure 1** Scheme of a spectroscopy oriented expert system. The data available on the unknown compound X (spectrum, constraints) form the input. All subsequent procedures are presented in rectangles, while intermediate results are shown in ellipses. At the point where the simulated spectra are obtained, they are compared with the original input spectra and the whole procedure stops if the result is satisfactory. If not, the user has the possibility of influencing certain steps (use another spectroscopy, add other constraints, change or add new rules, or make another selection of possible set of structural fragments), which is indicated by zigzagged arrows. (Reprinted with permission from Tušar L, Tušar M, Bohanec S, and Zupan J (1992)  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra simulation. *Journal of Chemical Information and Computer Sciences* 32: 299–303; © American Chemical Society.)

advantage of modeling systems designed for special purposes compared with classical expert systems is in a certain freedom in choosing possible solutions because of the feedback that rejects unreasonable results when the hypothesis is tested and evaluated.

The system must detect the cases when it is not able to produce a working hypothesis or when the hypothesis that has been created is causing the process to diverge ('explode'). If this happens, the system

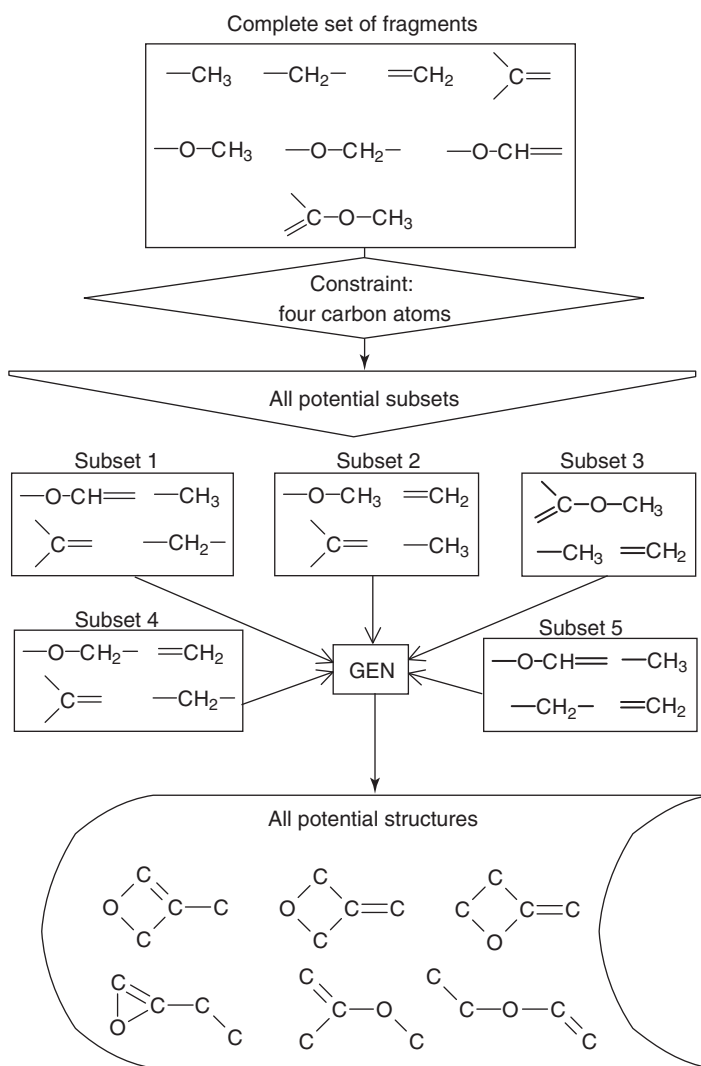

has to ask the user for more data constraints, for help in the selection of priorities among available hypotheses, and must accept suggestions from the user. Such an interaction from the user's side calls for an expert in the field and must be carefully recorded by the computer for possible feedback to the system in order to increase its knowledge.

The first complex procedure indispensable for all chemistry- and spectroscopy-oriented systems, as

well as for the procedures designed for special purposes, is a structure search. It can be implemented in three forms, i.e., as a substructure, as a superstructure, or as a maximal common structure search. If in the substructure search the input fragment is a complete structure, i.e., with no possible continuations given, the result can be either an exactly identical structure or no structure at all. A significant portion of the chemical and mathematical knowledge is built into the structure generator, or more precisely into the part of it that selects the constraints limiting the type of structures considered in the generation. The structure generator is a procedure that 'assembles' all topological possible structures from a given set of data: molecular formulas, set of fragments, etc. The problem may lead to an enormous number of

combinations (combinatorial explosion) that is computationally so intensive that, with the exception of the simplest molecular formulas, it is not possible to generate all potential structures. Therefore, the tree of structures has to be inspected only through the branches that represent the structures compatible with constraints given by the user (e.g., by considering only five- and six-membered rings, or no aromatic rings).

An indispensable procedure in such systems is the simulation of spectra from a known structure. The simulation of spectra can also be implemented as a stand-alone system. There are two different ways for solving the problem of simulations. The first is an *ab initio* calculation (from fundamental physical laws), while the second one is a heuristic or

**Figure 2** Selection of all possible subsets from the complete set of structural fragments and the resulting possible structures generated by the structure generator 'GEN'. (Reprinted with permission from Tušar M, Tušar L, Bohanec S, and Zupan J (1992)  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra simulation. *Journal of Chemical Information and Computer Science* 32(4): 299–303; © American Chemical Society.)

experience-based approach. Because of the excessive use of computer resources in the majority of cases, the *ab initio* approach is not suitable for implementation into the systems described in this section.

For the above reasons, the simulations are mainly performed in a heuristic and approximate way, using heuristic rules, statistical data, tables, semiempirical formulas, etc. For example, simulations can be made satisfactorily in various types of NMR spectroscopy, where long-range effects have much less influence compared to IR spectroscopy. IR spectra are very hard to simulate due to the 'spread' of vibrations through the entire structure. An interesting simulation technique is the determination of 'spectral contributions' of all fragments and atoms from large specialized collections of spectra with assigned structures. For the extraction of contributions a substructure search algorithm, which can search for a set of slightly different structural fragments, is required. The quality of the simulated spectrum obtained this

way depends on the size and quality of the collection for a particular spectroscopy. If the collection contains a structure very similar to the query, it is expected that the spectrum is similar as well and the available contributions are sufficient for the simulation of a good quality.

### Evaluation of the Hypothesis

Evaluation of the hypothesis, which may include simulated, retrieved, or calculated spectra, structures, and other features, is based mainly on the experience of human experts who set up the criteria and the coefficients according to which the evaluation is calculated. As discussed above, the distance between two spectra is relatively easy to evaluate, in contrast to the distance between two structures, which is very problem-dependent. In practice, we are looking for the relative similarity: which structure from the list of structures proposed in the hypothesis

**Table 1** Simulated  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of six possible structures

Structure no.	Structure	$^1\text{H}$ NMR spectrum (ppm)	$^{13}\text{C}$ NMR spectrum (ppm)
1		3.55, 3.55, 5.22, 5.22	74.2, 74.2, 106.5, 149.1
2		2.05, 3.55, 3.83, 3.90	39.4, 60.9, 78.4, 164.8
3		1.80, 4.35, 6.23	13.4, 74.1, 110.3, 135.6
4		1.00, 2.00, 6.24	7.5, 27.7, 105.7, 130.9
5		1.80, 3.50, 3.82, 3.90	23.7, 51.1, 76.5, 163.3
6	$\text{H}_5\text{C}_2\text{---O---CH=CH}_2$	1.30, 3.70, 4.04, 4.18, 6.47	14.8, 62.7, 83.5, 151.8
	Experimental	2.2 T, 3.6 S 3.8/4.1	20.8, 51.5, 76.7, 163.5

is more similar to the query? For this purpose some topological indices and distances are found to be suitable.

The most difficult of all evaluations is the final rating of how well the obtained structure or spectrum fits the input data. Probability measures should be available for each spectra–feature correlation. A simple mean value of all probabilities is a rough estimate of the accuracy of the result. The weights can be added to differentiate the influence of certain spectral regions or structural fragments on final evaluation of the hypothesis. In general, one spectroscopy is not enough to solve the structure completely; hence, data from different spectroscopies should be combined.

### Example

As an example of how the modeling techniques can be used, a real case where the  $^{13}\text{C}$  and  $^1\text{H}$  NMR simulations were employed to solve the unknown structure by the system CARBON is presented. The experimental data are  $^{13}\text{C}$  and  $^1\text{H}$  NMR spectra of the unknown.  $^{13}\text{C}$  NMR spectrum contains four peaks (at 20.8, 51.5, 76.7, and 163.5 ppm relative to the resonance line of tetramethylsilane – TMS) and  $^1\text{H}$  NMR spectrum consists of a triplet at 2.2 ppm, a singlet at 3.6 ppm, and a multiplet from 3.8 to 4.1 ppm, all relative to TMS. Using the ‘FRAGMENT’ option in the system CARBON, the two most common fragments at each  $^{13}\text{C}$  NMR peak were selected, yielding a set of eight fragments. From this complete set and the constraints of the target structure (four carbon atoms in the molecular formula), the module GENSTR has selected five possible subsets (Figure 2). From the five subsets, six different structures were generated.

For six possible structures  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were simulated. From the obtained results (Table 1) it is clearly seen that the structure no. 5 has produced the best pair of spectra compared with the experimental ones. Indeed, the unknown compound was 2-methoxypropene as proposed by the CARBON system.

### Introduction

Sublimation is not a procedure that is generally regarded as an analytical technique. It is a process, however, by which compounds can be purified or mixtures separated and as such can be of value as a single step or as an integral part of a more complex analytical method. It is applicable to a range of solids

of inorganic or organic origin in a variety of different matrices and can be particularly useful when heat-labile materials are involved.

As a method of sample purification sublimation has been used to produce high-purity materials as analytical standards. A specific and common example of sublimation used as a means of purification is the removal of water from heat-labile materials in the process known as freeze-drying. The technique is described more fully below.

As a separation technique fractional sublimation has been used either to purify samples for analysis by

removing undesirable components of the matrix or to remove the analyte from the matrix for subsequent analysis.

## Principles

Sublimation is the direct conversion of a solid to a gas or vapor:

The heat supplied in this endothermic process is termed the heat of sublimation ( $\Delta H_{\text{subl}}$ ). The conditions under which sublimation occurs may be predicted for a given substance from its phase diagram, but in practice it is more common to use typical experimental parameters to determine the optimized procedure.

The heat of sublimation is a crucial parameter in deciding upon the applicability of sublimation to a particular substance, or indeed on the possibility of separating two components in a mixture.

An empirical approach to determine the appropriate temperature and pressure for sublimation can be used based upon previously determined data. The temperature ( $T$ ) and pressure ( $P$ ) of sublimation can be related by an expression of the form:

$$\log_{10} P \text{ (mm)} = A - B/T$$

in which the constants  $A$  and  $B$  for compounds of interest are available from published tables. The result of the sublimation process can be seen in a freezer where ice sublimates and resolidifies as crystals. Iodine is a common substance that sublimates at room temperature and pressure; the result of this can be observed in a reagent bottle of the element.

The theory and mechanism of sublimation is of less practical importance to analytical procedures than it is in some other specialized areas of chemical science. Knowledge of sublimation characteristics can aid improvements in the stability of materials used at high temperatures or low pressures. For analytical purposes it should be sufficient to recognize that rates of sublimation depend upon the topology of the vaporizing surface (dislocations, atomic steps, and ledge concentrations) and upon any atomic rearrangement that occurs during the sublimation process.

Experimentally, to effect sublimation, a number of criteria need to be satisfied. First, the sample in question must be maintained at a temperature that ensures a sufficiently high vapor pressure for sublimation to occur, whilst remaining below that point at

which the material either decomposes or melts. Second, a secondary surface must be available on which the sublimed vapor can recondense or resolidify. A number of experimental arrangements have been used that allow these criteria to be established; these are described in a later section of this article. It is also possible to enhance the sublimation process by changing the physical parameters under which the process is carried out:

- The sample may be heated in order to increase its vapor pressure.
- The application of a vacuum to the apparatus encourages vaporization and enhances the sublimation.
- Selectively cooling part of the apparatus increases the efficiency of the condensation process.
- Using an entraining gas can improve the mass transport in the system and thereby increase the overall efficiency of the sublimation process.

## Apparatus

The simplest form of sublimation apparatus consists of a beaker or porcelain dish on top of which is placed an upturned watch-glass. The beaker contains the solid to be sublimed and the underside of the watch-glass provides the surface upon which the sublimed components condense (**Figure 1**). A perforated filter paper is commonly placed between the beaker and the watch-glass to prevent sublimate falling back into the sample.

A variant upon the above system uses an upturned funnel instead of a watch-glass as the condensing surface and an appropriately placed sealing ring improves the performance (**Figure 2**). Coils through which coolant is circulated can promote the sublimation process.

An early form of sublimation apparatus of which the above arrangements are derivatives (**Figure 3**) included a means of cooling the surface on which the sublimate condenses. Cooling can be achieved in a number of ways, for example, using filter papers moistened with cool water, or in the case of the upturned funnel, a suitably shaped coil of circulating coolant liquid can be placed around the surface.

Sublimation under reduced pressure uses a modified form of apparatus in which a sealed enclosure allows a vacuum to be applied. The cooled surface is orientated with respect to the sample so as to maximize the condensation once sublimation has occurred (**Figure 4**). Reducing the distance that the sublimed substance(s) must travel is beneficial provided the necessary temperature gradient between

**Figure 1** Simple apparatus for demonstrating the principles of sublimation. S, sample; P, sublimate (product); FP, perforated filter paper.

sample and condensing surface can be maintained. An alternative arrangement for sublimation applications is shown in **Figure 5**.

Freeze-drying, a special application of the sublimation principle, uses apparatus of a different kind (**Figure 6**). The sample, usually a liquid at room temperature, is dispersed around the walls of a round-bottomed flask whilst it is frozen by immersion in a suitable freezing mixture, for example, dry ice/acetone. The flask is then attached to the evacuating system that usually comprises an oil vacuum pump protected from the ice sublimate by a train of

**Figure 2** Apparatus for simple sublimation at atmospheric pressures. Watch-glass, W, with sample, S, surmounted by filter funnel, FF, with cooling coils, C, glass wool, G, and collected sublimed product, P. A sealing ring, R, is included between the watch-glass and filter funnel.

**Figure 3** Early form of sublimation apparatus. The heated crucible, CR, rests in the cooling device. The sublimate product, P, collects on the underside of the watch-glass, W. S, sample; P, sublimed product.

condenser traps. Over a period of typically several hours the ice sublimates from the sample and condenses in the traps. Air is then admitted to the

**Figure 4** Apparatus for sublimation at reduced pressure. Coolant is circulated through the cold finger, CF, whilst a vacuum is applied to the sample chamber.

apparatus and the dried sample can be removed whilst the sublimed ice is drained off as water through the drain tap. Frequently, this system is used to dry heat-sensitive materials such as enzymes and the process has been termed lyophilization.

Sublimation of metallic elements from rock or ore samples requires high temperatures. The equipment used is based upon silica furnace tubes in order to withstand the necessary conditions. The silica tube is heated in a furnace and the sublimate condenses either on a cool part of the tube or on a cooled surface immediately after leaving the tube.

The conditions of sublimation must be chosen according to the requirements of the application. For simple purification the sample temperature is raised slowly, under reduced pressure if necessary, until the sublimate is observed on the condensing surface. These established conditions should then be maintained until no further sublimation appears to be occurring, at which point the sample temperature can be raised again if other components of the sample can be further removed. At any point in this cycle the apparatus can be dismantled and the sublimate removed. This process allows selective separation or fractional sublimation to be carried out.

**Figure 5** Improved sublimation apparatus proposed by Eisenbraun *et al.* (1978). Sample, S, sublimates from the lower to the upper chamber where condensation takes place on the cooled surface, C, improves the condensation process. A specially formed spatula, SP, can be used to help remove the sublimate after the upper part of the apparatus is removed.

## Applications

Sublimation is applicable to a wide range of organic and inorganic compounds in an equally wide range of different matrices. Sublimable substances include ice, iodine, arsenic(III) oxide, cadmium sulfide, ammonium chloride, and a large number of organic compounds. Common matrices from which substances are sublimed include biological fluids, plant materials, carbonaceous materials, samples of crude organic solids, and samples of rocks and ores.

Sublimation as a method of applying substances to thin-layer chromatography (TLC) plates involves the sample being sublimed and the vapor produced being directed by means of a drawn capillary onto the

**Figure 6** Typical freeze-drying apparatus. The frozen sample, S, is attached to the condenser assembly and a vacuum is applied. A cold trap, CT, protects the pump as ice sublimates from the sample and subsequently condenses in the refrigerant condensers, RC. On completion of the drying the sample is removed and the collected ice melts and drains from the system through the stopcock, SC.

surface of a TLC plate that is slowly moved in one dimension. This results in the sublimed materials being deposited upon the TLC plate in a differential mode – the most easily sublimed compounds are deposited first whilst those requiring a higher temperature are deposited later. The TLC plate is then developed in the normal way to give what has been termed a ‘thermofractogram’ in which the substances are separated as a function of their heats of sublimation along one axis and as a function of their chromatographic characteristics along the other axis. This approach has been applied to a wide range of substances including pharmaceutical preparations, plant components, and foodstuffs.

Only a very limited number of standard methods are reported in which sublimation is an important aspect. These comprise an ASTM standard for measurement of sublimation from thermionic emitters, and two standards from Germany and Japan testing the stability of dyes and printing inks to sublimation. The first covers the determination of the quantity, rate, and identity of sublimed, evaporated, or sputtered materials, whilst the latter two are concerned with textile materials and semimanufactured products.

Sublimation of ninhydrin crystals has recently been reported as providing a significant improvement in detecting fingerprints on thermal paper. Sublimation allows fine detail of latent fingerprints to

become visible without the usual background staining experienced with the application of ninhydrin solutions. The method is applicable to the new Euro monetary notes.

Sublimation is often the mechanism by which pre-concentration of an analyte is effected, although this fact is frequently not appreciated. Dynamic headspace concentration from solid samples such as plant materials, foodstuffs, or polymeric materials occurs by sublimation of the volatile components. Indeed, given appropriate apparatus that can be operated at different temperatures for dynamic headspace concentration, the heat of sublimation can be determined for various compounds.

Derivatization procedures carried out on crude samples can produce materials with improved sublimation characteristics. This technique has been used to produce volatile compounds of lanthanides and actinides that have then been sublimed prior to analytical determinations. Derivatives have been made using  $\beta$ -diketones (hexafluoroacetylacetone or acetylacetone), benzoyltrifluoroacetone, and thenoyltrifluoroacetones.

Low-temperature sublimation, which in some circumstances is termed freeze-drying, has been used to separate water, as ice, from biological fluids such as serum, urine, or saliva. The technique has been particularly useful in pediatric cases where sample volumes have been extremely low. Determinations have then been accomplished using infrared spectroscopy or mass spectrometry. Preparation of physiological samples for determination of deuterium oxide has included sublimation techniques prior to spectrophotometric determinations.

Low-temperature sublimation has been used to prepare samples for cryo-scanning electron microscopy (SEM) analysis in order to examine herbicide particles in a water suspension. The sublimation of herbicide-containing frozen water droplets provides a suitable etching of the surface for the SEM technique.

High-temperature sublimations are often the methods of choice in sample preparations from mineral ores, particularly in the case of trace enrichment of noble metals and the actinides and lanthanoids prior to activation methods. Temperatures of 800–1200°C are typical. The procedure is carried out in silica tubes with entrainment gases, for example, air or argon, being used to increase the sublimation process.

Polycyclic aromatic compounds have been separated using sublimation techniques from a variety of samples including coal, solids derived from oil, coal, and petroleum processing, and residues (soots) resulting from the use of such fossil fuels.

A variety of miscellaneous applications have been developed for separation from difficult matrices and purification of specific materials. These include:

- Mercury separated from impurities by conversion to its iodide followed by sublimation.
- Isolation of proazulene and chamomile from the flower heads of plants.
- Isolation of aroma compounds from wheat and rye samples prior to determination using isotope dilution methods.
- Determination of tin in cassiterite.
- Selective sublimation of molybdenum and tungsten.

Sublimation is used in some procedures for the preparation of samples for SEM in which gold is sublimed in vacuum from a heated tungsten filament to the sample being examined.

## Introduction

In this article, the techniques most commonly employed for elemental sulfur determination are introduced. They are compared in the form of tables where relevant recent information such as detection limits and typical samples have been collected. Also, general information on the element sulfur is provided.

## Origin and Nature

Sulfur naturally consists of four stable isotopes  $^{32}\text{S}$  (95%),  $^{33}\text{S}$  (0.76%),  $^{34}\text{S}$  (4.22%), and  $^{36}\text{S}$  (0.014%). The atomic number of sulfur is 16 and its atomic weight is  $32.066\text{ g mol}^{-1}$ . It has the most allotropes of any element, the most stable of these being orthorhombic  $\text{S}_8$ . Commercial sulfur melts at  $\sim 119^\circ\text{C}$  and boils at  $444.6^\circ\text{C}$ . Its density varies from  $1.808\text{ g cm}^{-3}$  at  $115^\circ\text{C}$  to  $1.599\text{--}1.614\text{ g cm}^{-3}$  at the boiling point. Sulfur is an odorless, tasteless, and brittle solid. It is a poor conductor of heat and electricity. Pure solid sulfur is pale yellow. It is stable to air and water but burns if ignited. Almost all the

elements, apart from gold, platinum, and the inert gases, combine with sulfur.

Sulfur is found both in its native form and in metal sulfide ores. It occurs in its native form in the vicinity of volcanoes and hot springs. Sulfur is the 10th most abundant element, and it is found in meteorites, in the ocean, in the earth's crust, in the atmosphere, and in practically all plant and animal life. The abundance of sulfur in the earth's crust is 0.03–0.1%. Sediments (sulfur concentration  $\sim 4250\text{ }\mu\text{g g}^{-1}$ ) have accumulated a large proportion (43%) of the total sulfur of the earth's crust. Metamorphic and magma rocks, which are the other typical materials of the crust, contain less sulfur (concentration  $\sim 600\text{ }\mu\text{g g}^{-1}$ ). Pyrite is the most common mineral form of sulfur in sediments. The storage of sulfur in sediments and ocean crusts (the sulfur concentration of seawater is  $\sim 900\text{ }\mu\text{g g}^{-1}$ ) is balanced by the degassing of volcanic rocks. High-purity sulfur is commercially available in purities of 99.999% +.

## Common Matrices in which Sulfur is Found

Sulfur occurs in organic substances, e.g., eggs, hair, wool, albumin, garlic, mustard, horseradish,

## Introduction

In this article, the techniques most commonly employed for elemental sulfur determination are introduced. They are compared in the form of tables where relevant recent information such as detection limits and typical samples have been collected. Also, general information on the element sulfur is provided.

## Origin and Nature

Sulfur naturally consists of four stable isotopes  $^{32}\text{S}$  (95%),  $^{33}\text{S}$  (0.76%),  $^{34}\text{S}$  (4.22%), and  $^{36}\text{S}$  (0.014%). The atomic number of sulfur is 16 and its atomic weight is  $32.066\text{ g mol}^{-1}$ . It has the most allotropes of any element, the most stable of these being orthorhombic  $\text{S}_8$ . Commercial sulfur melts at  $\sim 119^\circ\text{C}$  and boils at  $444.6^\circ\text{C}$ . Its density varies from  $1.808\text{ g cm}^{-3}$  at  $115^\circ\text{C}$  to  $1.599\text{--}1.614\text{ g cm}^{-3}$  at the boiling point. Sulfur is an odorless, tasteless, and brittle solid. It is a poor conductor of heat and electricity. Pure solid sulfur is pale yellow. It is stable to air and water but burns if ignited. Almost all the

elements, apart from gold, platinum, and the inert gases, combine with sulfur.

Sulfur is found both in its native form and in metal sulfide ores. It occurs in its native form in the vicinity of volcanoes and hot springs. Sulfur is the 10th most abundant element, and it is found in meteorites, in the ocean, in the earth's crust, in the atmosphere, and in practically all plant and animal life. The abundance of sulfur in the earth's crust is 0.03–0.1%. Sediments (sulfur concentration  $\sim 4250\text{ }\mu\text{g g}^{-1}$ ) have accumulated a large proportion (43%) of the total sulfur of the earth's crust. Metamorphic and magma rocks, which are the other typical materials of the crust, contain less sulfur (concentration  $\sim 600\text{ }\mu\text{g g}^{-1}$ ). Pyrite is the most common mineral form of sulfur in sediments. The storage of sulfur in sediments and ocean crusts (the sulfur concentration of seawater is  $\sim 900\text{ }\mu\text{g g}^{-1}$ ) is balanced by the degassing of volcanic rocks. High-purity sulfur is commercially available in purities of 99.999% +.

## Common Matrices in which Sulfur is Found

Sulfur occurs in organic substances, e.g., eggs, hair, wool, albumin, garlic, mustard, horseradish,

cabbage, and many proteins. It also occurs in natural gas, petroleum, and coal. It is a minor constituent of fats, body fluids, and skeletal minerals. The element is commonly determined in environmental samples such as air particulates, water, and soil samples. Sulfur makes up a large proportion of the fine particulate matter found in atmospheric aerosol samples.

## Methods of Determination at Major and Trace Element Levels

Total sulfur can be determined by several techniques. In the more conventional chemical methods sulfur is converted to, e.g., oxides and then determined by infrared (IR) or gravimetric techniques or converted to hydrogen sulfide and then determined by gas-analysis techniques. Here, mainly methods used for the determination of elemental sulfur (direct methods) are considered; methods used for sulfur compound analysis are dealt with elsewhere in the Encyclopedia. Also, techniques used for radioisotope detection, for example, the multiphoton detection are excluded from the present survey. Readers interested in chromatographic and electrophoretic techniques employed for sulfur and sulfur-oxygen species analysis can consult also the review articles listed in the Further Reading section. The methods are divided into three main groups: general analytical methods, activation methods, and prompt ion beam methods. In order to find the most recent figures of merit and applications, computerized key word searches were performed using several databases. The collected important data concerning the methods and applications are summarized in Tables 1–4.

### General Analytical Techniques

In the following the various common analytical techniques are discussed briefly. The methods surveyed have been frequently used as routine methods for elemental analysis in laboratories, and easy-to-use apparatus have been developed for most of the commercially available methods. Details of the applicability of the methods to sulfur analysis are outlined in Table 1.

**Atomic spectrometry** Laser-induced atomic emission spectroscopy (AES) is a fast technique to determine directly elemental sulfur. Practically no matrix effects occur and the method is virtually nondestructive and easy to use. A disadvantage is the rather poor sensitivity, for example, a typical detection limit for sulfur in steel is  $\sim 70 \mu\text{g}$  per g. With indirect atomic absorption spectrometry clearly better

sensitivity is obtained, a detection limit of  $0.27 \mu\text{g}$  per g in soil has been achieved. The method needs, however, chemical pretreatment of the samples.

Different inductively coupled plasma (ICP) methods have been developed which can be used for sulfur analysis. Of these, ICP-AES or ICP-OES (optical emission spectroscopy) and ICP-MS (mass spectrometry) have been widely used. Both have a very broad analytical range.

In ICP-AES, intensity of the S emission spectrum is a direct function of sulfur concentration in a solution and does not depend on the type of sulfur-containing compound and the oxidation status of the analyzed sulfur atom. The method is subject to a large variety of spectral interference from various sources but these can be minimized by using high-resolution spectrometers and vacuum purge optics. The method is notable for its considerably low detection limits, wide dynamic range, and elemental coverage. It is used most in the field of environmental analysis but is of limited use without sample preconcentration. When the method is used to determine sulfur, its detection limit is substantially higher than the typical (nanogram per milliliter) values cited for most metals.

**Mass spectrometry** ICP-MS offers an accurate method for sulfur isotopic ratio measurements and a sensitive technique for elemental sulfur determination. The method may be applied as an absolute method, because the analyzed atoms themselves, and not the radiation they emit, produce the analytical signals. The technique is useful for the analysis of high-purity materials, such as metals and semiconductors. The detection limits obtainable in most cases by ICP-MS are considerably better than typical values reported for ICP-AES. However, the analytical precision and accuracy of the method are often poor. The utility of the method to determine sulfur is further complicated, as efficient ionization of sulfur is difficult to obtain because of the high ionization energy of the element.

There are also various sources of interference inherent in the method. The use of mass spectrometric methods for sulfur analysis is complicated by the isobaric interferences of  $^{16}\text{O}^{16}\text{O}^+$ ,  $^{16}\text{O}^{17}\text{O}^+$ , and  $^{16}\text{O}^{18}\text{O}^+$  for  $^{32}\text{S}^+$ ,  $^{33}\text{S}^+$ , and  $^{34}\text{S}^+$  analysis, respectively. Also, other possible polyatomic isobaric interferences, such as  $^{14}\text{N}^{18}\text{O}^+$  and  $^{15}\text{N}^{16}\text{O}^+$ , should be taken into account. Another problem has been the plural oxidation states of sulfur. Several procedures have been developed to minimize these problems, such as the use of the electrothermal vaporization technique, use of a hexapole filter, and a sector magnetic field to reduce molecular ions

**Table 1** Conventional analytical methods for sulfur determination

Method	Mass/volume needed	Interferences	Multielement method	Destructive	Typical samples	Typical detection limit	Remarks

causing interference. Also, a dynamic reaction cell has been employed to oxidize sulfur to allow its detection as  $\text{SO}^+$ .

Sulfur isotope ratios  $^{34}\text{S}/^{32}\text{S}$  are known to vary significantly in nature and their determination has become of wide interest in, e.g., geochemical, biological, environmental, and industrial studies. ICP-MS provides a precise method for such isotope ratio determinations.

In secondary ion mass spectrometry (SIMS), secondary ions produced by primary low-energy ion bombardment are analyzed with a mass spectrometer. Sulfur has one of the highest relative secondary negative ion yields and is therefore very sensitive for SIMS detection using  $\text{Cs}^+$  as primary ions. SIMS is extensively used, especially in semiconductor technology, and has extreme detection limits and a wide dynamic range. Using the microvolume SIMS procedure nanoliter volumes of solution is sufficient for typical analyses. This technique is also commonly used for obtaining concentration–depth profiles. The problems encountered with SIMS in this case are related to calibration of both the concentration and depth scales. Persistent problem with SIMS is the dependence of the ion yield on the chemical composition of the matrix.

**Coupled chromatographic techniques** Several chromatography techniques (C) have been used for sulfur determination. These techniques allow generally very sensitive detection of sulfur-containing compounds (see Table 1). Usually, sulfur is first oxidized followed by ion chromatography. Typically, such analyses require sophisticated chemical procedures but this is not always the case; for example, the technique using pyrolysis-gas chromatography (Py-GC) equipped with a flame photometric detector (FPD) does not require sample pretreatment.

**Auger spectroscopy** Auger electron spectroscopy is a powerful surface analysis technique, as the analytical signals come from the top few monolayer of the specimen. In this technique, a primary beam of electrons is used to produce inner shell vacancies in atoms of the specimen. This method has been used for the determination of sulfur, e.g., on GaAs surfaces and to study sulfur surface segregation in Ni–Al solid solutions and the adsorption on a GaAs (001) surface by hydrogen sulfide exposure and heat treatment.

**X-ray fluorescence spectrometry** Conventional energy-dispersive X-ray fluorescence (XRF) has been widely used for sulfur determination by using a

chromium or copper anode in the X-ray tube. The determination of sulfur by X-ray detection poses several practical problems. As the energy of the characteristic X-rays is low (S-K $\alpha$  2.307 keV) absorption problems play an important role. Also the fluorescence yield of sulfur is rather low. The low-energy SK X-rays are usually measured in a vacuum, preferably by a windowless (or ultrathin window) X-ray detector. As a result, with techniques based on the detection of characteristic X-rays the achievable detection limits for sulfur are rather poor. For accurate sulfur determinations also large amounts of sample material and standards are required. An advantage of XRF is that chemical species analysis can be carried out by a high-resolution spectrometer.

The total reflection of primary X-rays (TXRF) has been employed to improve the XRF detection limits by decreasing the radiation-induced background. In a typical analysis, the sample material is prepared as a thin film, placed on a polished, optically flat carrier, and irradiated via a very small angle. TXRF is a convenient analysis technique because of the low sample masses required. The major drawback of this method is that only thin-film-type samples can be analyzed. It has been used for sulfur analysis from environmental, mineralogical, and biological samples.

Synchrotron radiation induced wavelength-dispersive XRF has gained increased attention as a sensitive technique for various analytical applications. It has been used, for example, in the analysis of ion-implanted sulfur from silicon wafers.

### Nuclear Activation Methods

Several methods are based on the measurement of radiation resulting from nuclear reactions induced either by neutrons, charged particle, or high-energy photon irradiation. These methods are generally multielemental and nondestructive.

**Neutron activation analysis** Neutron activation analysis (NAA) is not generally considered as a practical method for sulfur determination, but several reactions employing fast (14 MeV) or thermal neutrons may be used. The various applications of NAA have been collected in Table 2.

**Charged particle activation analysis** The method based on charged particle activation analysis utilizes delayed instrumental or radiochemical measurement of nuclear reaction-produced radionuclides in the same manner as in NAA. It differs from the other activation analysis techniques because of the limited penetration range of the charged particles used. This feature, however, is advantageous as it allows

**Table 4** Charged particle based prompt methods for sulfur

Method	Reaction	Ion/energy (MeV)	Measurement time/collected charge	Sample	Detection limit	Remarks	
PIXE		H <sup>+</sup> /3	3 $\mu$ C	Single animal cell	7.5 $\mu$ g per g	Microbeam, spatial resolution 1 $\mu$ m	(a)

near-surface analysis. The charged particles used in sulfur detection are usually protons (see Table 3 for details). Medium energy tritium beams (3–12 MeV) have also been used.

**Photonuclear activation analysis** In photonuclear activation analysis, high-energy photon irradiation of a sample is used to produce radionuclides that are subsequently measured by  $\gamma$ -ray spectroscopic methods.

These energetic photons, like neutrons, are capable of penetrating into thick solid samples. This allows bulk analysis without chemical pretreatment. A drawback of this method is the large sample mass required.

### Prompt Ion Beam Methods

The best known prompt accelerator based methods suitable for sulfur determination are particle-induced

X-ray emission (PIXE), heavy ion-induced X-ray emission (HIXE), particle-induced  $\gamma$ -ray emission (PIGE), Rutherford backscattering spectrometry (RBS), and elastic recoil detection analysis (ERDA). These methods are also multielemental and nondestructive. In general, when ion beam methods are used it should be kept in mind that sulfur-containing matter may be lost during the irradiation, and therefore sufficiently low beam currents should be employed. Also, sample homogeneity is vital since the volume probed by the ions is rather small.

**Particle-induced X-ray emission** In PIXE, mainly 1–3.5 MeV protons are used as bombarding particles. There are several studies in the literature concerned with investigations of the optimum bombarding proton energy for sulfur analysis. According to these findings, 1 MeV protons provide the best detection limits for sulfur analysis. As sulfur vaporizes easily when bombarded in a vacuum, an external beam mode where the particle beam is extracted into the ambient through a thin exit foil has been frequently used. The best results for sulfur analysis are obtained if helium is used as the ambient. Many types of samples have been analyzed for sulfur by PIXE; for example, aerosols collected on a filter, pigments, algae, artifacts, glass, and fingernails. The use of proton microprobes for elemental mapping (including sulfur) using PIXE has recently gained more interest in environmental and biological studies. A 2 MeV deuteron bombardment technique has also been tested simultaneously with nuclear reaction measurements for sulfur analysis. However, the sensitivity obtained is not as good as that with protons. Low-energy (below 10 MeV) heavy ion beams (HIXE) may be successfully used for sulfur analysis. Heavy ion induced X-ray satellite emission (HIXSE) spectroscopy together with efficient, high-resolution spectrometer has been used to obtain chemical information from sulfur-containing matrixes. For details, see Table 4.

**Particle-induced  $\gamma$ -ray emission** In PIGE, the prompt  $\gamma$ -rays from various reactions are detected during irradiation. Tritons ( $^3\text{H}$ ) as well as protons have been used as bombarding particles in this application. Alpha-particles do not produce  $\gamma$ -rays from sulfur bombardment at practical ion energies.

Of the several applicable reactions for this application,  $^{32}\text{S}(\text{p},\text{p}'\gamma)$  is the most frequently used. Information on the reactions used is collected in Table 4. An important advantage of PIGE with protons is the possibility of performing light element depth profiling. The method is based on the fact that in the megaelectronvolt energy range, the cross-sections for

reactions between protons and light nuclei exhibit sharp resonances. For sulfur depth profiling via the nuclear resonance broadening method, the resonance at 677 keV proton energy of the reaction  $^{34}\text{S}(\text{p},\gamma)$  has been employed successfully.

**Rutherford backscattering spectrometry and elastic recoil detection analysis** Conventional RBS analysis may be used for thin film sulfur analysis. Although the method in this case is not very sensitive, it has the advantage that depth profiles for sulfur and film thicknesses may be obtained using it. Ion channeling can be taken advantage of for studying near surfaces of crystalline materials. For example, microprobe channeling has been combined with PIXE analysis to determine the lattice location of sulfur in crystalline materials.

Heavy ion recoil spectroscopy can be used for analysis of surface layers and it has shown its usability as a characterization method especially to meet the needs of the semiconductor industry. The main reason for its success is that it provides depth profiling of all the sample atoms in one measurement. An example of a typical application of heavy ion ERDA is provided in Table 4.

### Miscellaneous Analytical Techniques

Laser-induced breakdown spectrometry enables simultaneous analysis of various elements in a short time. The obtained sensitivity for sulfur is not, however, as good as with the ICP techniques. For example, a detection limit of 45  $\mu\text{g}$  per g for sulfur in steel has been obtained using this technique.

Spectrochemical methods such as IR detection of  $\text{SO}_2$  formed after high-temperature combustion require large amounts of sample material and also standards for accurate sulfur determination. A detection limit of 0.2  $\mu\text{g}$  per g has been reported for sulfur in high-purity iron by this technique.

Flame photometric detection allows a fast and fully automated means for sulfur analysis. Typical limits of detection obtainable are 1.2 ng for solids and 0.2 ng for liquids.

Accurate determination of elemental sulfur in petroleum and its distillates (petroleum products) is of significant industrial importance. It is being determined routinely by several techniques, for example, by the differential pulse polarography technique. The detection limit is 0.1  $\mu\text{g}$  per g, but chemical treatment of the sample is needed. The wet chemical method of activated Raney nickel has been successfully employed with a detection limit of 0.1  $\mu\text{g}$  per g. Also in this case preconcentration of sulfur is needed. By using the Houston Atlas sulfur analyzer in which

total sulfur is reduced to  $\text{H}_2\text{S}$  a detection limit of  $<20 \text{ ng g}^{-1}$  can be achieved.

Electrode materials of electrochemical cells have been analyzed by a method in which free sulfur is first isolated from the sample by solvent extraction and then determined by molecular emission cavity analysis. The lowest limit of detection for free sulfur that can be analyzed is  $0.8 \mu\text{g per g}$ .

An objective evaluation of the methods on the basis of literature data is hardly possible, because of differences in experimental conditions, sample, amount of sample available, and measurement time. Therefore, the detection limit values stated in the literature given in **Tables 1–4** should be considered, at best, approximate. But it is clear that there is no single instrumental technique that meets all the analytical requirements. For example, some methods may be applicable over only a limited concentration range, may be subject to matrix effects or spectral interferences, or have a limited availability. Also, sometimes nondestructive fast methods are needed. The choice of an instrumental method depends on the material to be analyzed and the type of analysis required.

## Areas of Special Interest, Use, and Safety Considerations

The uses of sulfur are many and varied. Large quantities of elemental sulfur are used in the vulcanization of natural rubber, in lime–sulfur sprays to destroy plant parasites, in the manufacture of artificial fertilizers and certain types of cements and electric insulators, in certain ointments and medications, and in the manufacture of gunpowder and matches. Sulfur is a critical element in defining the physical properties of steel. It is a contaminant element originating from the blast furnace iron-making process and not desired at high levels. In controlled amounts it can, however, improve the machinability of steel. Sulfur is known also to have an important influence on the magnetic properties and embrittlement of some alloys. As an example of the new uses of sulfur is its key role in the formation of filled carbon nanotubes in nanotechnology.

Most of the sulfur currently used is burnt to form sulfur dioxide for the use in the pulp and paper industry, for bleaching, and for conversion to sulfuric acid. Sulfuric acid is generally considered to be the most important manufactured chemical. Compounds of sulfur have many commercial uses, for example, in the manufacture of chemicals, textiles, soaps, fertilizers, leather, plastics, refrigerants, bleaching agents, drugs, dyes, paints, paper, refined petroleum, and other products.

Due to the wide use of sulfur and its compounds, analytical applications for sulfur determination are needed in many fields of, e.g., technology, biology, environment, medicine, geology, fine arts, and archaeology. As sulfur is often a common industrial pollutant, testing environmental samples for the element has become a matter of significant interest.

Sulfur is a nontoxic element. However, carbon disulfide, hydrogen sulfide, and sulfur dioxide should be handled carefully. Small concentrations of hydrogen sulfide can be metabolized, but at higher concentrations it can quickly cause death by respiratory paralysis. It is insidious in that it quickly deadens the sense of smell. Sulfur dioxide is a dangerous component in atmospheric air pollution.

## Overview

**T A Berger**, Berger Instruments, Newark, DE, USA

© 2005, Published by Elsevier Ltd.

## Introduction

Supercritical fluid chromatography (SFC) can be viewed as a subset of high-performance liquid chromatography (HPLC), sharing much of the same hardware and methodology. As in all chromatography, individual components of complex mixtures are separated from each other by differential interaction between a stationary phase and a mobile phase. In SFC, the mobile phase consists of a relatively dense, compressible fluid 'that acts as a solvent'. Instrumentally, the biggest difference between HPLC and SFC is the inclusion of a backpressure regulator downstream of most detectors that prevents the compressed mobile phase from expanding to a gas until after the separation is complete.

The name 'supercritical fluid' is obscure and confusing. Fluids have a characteristic 'critical point', discovered ~180 years ago, consisting of a critical temperature and pressure. Above (or 'super'-meaning above) this critical point, no increase in pressure, or temperature can cause two phases to form.

In a phase diagram, solid lines represent conditions where two phases are in contact. Crossing a line requires a phase transition and a massive energy transfer. A phase diagram of pure carbon dioxide is presented in **Figure 1** showing the regions of temperature and pressure defined as gas, liquid, and solid. The long diagonal line indicates the conditions where gas is in equilibrium with liquid. To the right, this line ends at the critical point. Some people

incorrectly draw horizontal and vertical lines (often dashed) extending from the critical point to the right and up to outline the supercritical region. There is no phase transition between a liquid and a supercritical fluid or between a gas and a supercritical fluid and such lines should not be drawn.

In SFC, the fluid must act as a solvent for the solutes of interest. Secondly, it should exhibit physical and chemical characteristics equal to or superior to normal solvents used as the mobile phase in HPLC. Two of the more intriguing characteristics of the fluids of interest are high diffusivity and low viscosity.

## Why SFC?

### Higher Diffusivity Equals Higher Speed Chromatography

In chromatography, the speed of separations is dictated in part by how fast the solute diffuses in the mobile phase. Generally, the more dense the mobile phase, the slower the diffusion and slower the separation. Typical solute binary diffusion coefficients ( $D_{1,2}$ ) in the gases used as the mobile phase in gas chromatography (GC) are in the order of  $0.1\text{--}1\text{ cm}^2\text{ s}^{-1}$ , while in liquids used as the mobile phase in HPLC are in the order of  $10^{-5}\text{ cm}^2\text{ s}^{-1}$ . In SFC using carbon dioxide as the mobile phase,  $D_{1,2}$  can be as high as  $10^{-3}\text{ cm}^2\text{ s}^{-1}$  when the fluid density is below  $0.1\text{ g cm}^{-3}$ , to as low as  $10^{-4}\text{ cm}^2\text{ s}^{-1}$  when the density approaches  $1\text{ g cm}^{-3}$ . Note that even at liquid-like densities, the diffusion coefficient remains substantially higher in the supercritical (and 'near-critical') fluid.

Higher diffusion coefficients translate directly to higher speed chromatography as indicated in the van Deemter equation. **Figure 2** is a van Deemter plot of plate height (HETP) versus linear velocity for both

## Introduction

Supercritical fluid chromatography (SFC) can be viewed as a subset of high-performance liquid chromatography (HPLC), sharing much of the same hardware and methodology. As in all chromatography, individual components of complex mixtures are separated from each other by differential interaction between a stationary phase and a mobile phase. In SFC, the mobile phase consists of a relatively dense, compressible fluid 'that acts as a solvent'. Instrumentally, the biggest difference between HPLC and SFC is the inclusion of a backpressure regulator downstream of most detectors that prevents the compressed mobile phase from expanding to a gas until after the separation is complete.

The name 'supercritical fluid' is obscure and confusing. Fluids have a characteristic 'critical point', discovered ~180 years ago, consisting of a critical temperature and pressure. Above (or 'super'-meaning above) this critical point, no increase in pressure, or temperature can cause two phases to form.

In a phase diagram, solid lines represent conditions where two phases are in contact. Crossing a line requires a phase transition and a massive energy transfer. A phase diagram of pure carbon dioxide is presented in **Figure 1** showing the regions of temperature and pressure defined as gas, liquid, and solid. The long diagonal line indicates the conditions where gas is in equilibrium with liquid. To the right, this line ends at the critical point. Some people

incorrectly draw horizontal and vertical lines (often dashed) extending from the critical point to the right and up to outline the supercritical region. There is no phase transition between a liquid and a supercritical fluid or between a gas and a supercritical fluid and such lines should not be drawn.

In SFC, the fluid must act as a solvent for the solutes of interest. Secondly, it should exhibit physical and chemical characteristics equal to or superior to normal solvents used as the mobile phase in HPLC. Two of the more intriguing characteristics of the fluids of interest are high diffusivity and low viscosity.

## Why SFC?

### Higher Diffusivity Equals Higher Speed Chromatography

In chromatography, the speed of separations is dictated in part by how fast the solute diffuses in the mobile phase. Generally, the more dense the mobile phase, the slower the diffusion and slower the separation. Typical solute binary diffusion coefficients ( $D_{1,2}$ ) in the gases used as the mobile phase in gas chromatography (GC) are in the order of  $0.1\text{--}1\text{ cm}^2\text{ s}^{-1}$ , while in liquids used as the mobile phase in HPLC are in the order of  $10^{-5}\text{ cm}^2\text{ s}^{-1}$ . In SFC using carbon dioxide as the mobile phase,  $D_{1,2}$  can be as high as  $10^{-3}\text{ cm}^2\text{ s}^{-1}$  when the fluid density is below  $0.1\text{ g cm}^{-3}$ , to as low as  $10^{-4}\text{ cm}^2\text{ s}^{-1}$  when the density approaches  $1\text{ g cm}^{-3}$ . Note that even at liquid-like densities, the diffusion coefficient remains substantially higher in the supercritical (and 'near-critical') fluid.

Higher diffusion coefficients translate directly to higher speed chromatography as indicated in the van Deemter equation. **Figure 2** is a van Deemter plot of plate height (HETP) versus linear velocity for both

**Figure 1** Phase diagram of carbon dioxide. The supercritical region is to the right and above the critical point at the end of the line separating vapor from liquid (sometimes called the boiling line).

**Figure 2** A van Deemter plot of plate height (plate height = HETP = height equivalent of a theoretical plate) vs. linear velocity showing that SFC exhibits similar, low (good) plate heights but at much higher velocities (and flow rates) compared to HPLC. Lines A, B, and C represent efficiency vs. flow on 10, 5, and 3  $\mu\text{m}$  particles, respectively. Lines D and E represent HPLC on 10 and 3  $\mu\text{m}$  particles, respectively.

packed column HPLC and SFC using several different sized particles. The figure shows that the optimum linear velocity in SFC, yielding the lowest plate height, is substantially higher than the optimum velocity in HPLC, yielding the same plate height. Thus, the same quality of separation is achieved in less time in SFC compared to HPLC.

Similarly, low viscosity allows fluids to be pumped at higher linear velocities (flow rates) without the pressure drop across the column becoming excessive.

The desired high diffusivity and low viscosity results from the lack of strong intermolecular forces between solvent molecules. After all, if there were strong intermolecular forces, the solvent would condense to form a liquid. Without such strong interactions, the solute molecules are less impeded as they diffuse through the fluid. Despite weak intermolecular forces, when an external force is applied to push the molecules close together, they collectively act as a solvent.

### Subcritical, Near-Critical, and Enhanced Fluidity Chromatography

For years, some users have differentiated between just subcritical and just supercritical conditions. This is an artificial distinction. For example, there has been an increase in the use of very hot water as a mobile phase. As the temperature is increased above 100°C, a backpressure regulator is required to keep the fluid from boiling (as in SFC). As temperature increases, diffusivity increases, while viscosity decreases, similar to SFC. The dielectric constant decreases, and water becomes less 'polar'. Temperature programming (usually from high to low temperatures) of pure water allows polarity tuning. The only negative aspect of water is the high temperatures required. Solute molecules and columns must be stable in water up to at least 300°C. This technique is sometimes called high-temperature HPLC or enhanced fluidity chromatography.

The general confusion about the physical and chemical meaning of the words 'super' and 'critical' has led to a plethora of terms such as 'subcritical' fluid chromatography, 'near-critical' fluid chromatography, and 'enhanced fluid' chromatography to deal with the fluids when they are nearly but not quite 'super' critical. All these names, including SFC, actually describe the same technique.

A subcritical fluid by definition is a liquid (or possibly a gas). Many workers have assumed that since some of the fluids used in SFC are defined as liquids they must have more typical liquid-like characteristics, such as much lower solute binary diffusion coefficients. Thus, crossing the border from just supercritical to just subcritical was assumed to cause a major change in physical properties (and was the tacit reason for the multiple names and the dashed lines in phase diagrams). To the contrary, some of the earliest work showed that diffusivity does not change significantly when the 'definition' of the fluid changes from just supercritical to just subcritical. There is no discontinuity, no change in slope, and nothing to support such assumptions. A plot of diffusion coefficients versus the reciprocal of temperature ( $1/T$ ), such as in Figure 3, produces a straight line even though the defined state changes from super- to subcritical in the middle of the temperature range.

SFC is actually misnamed because both just supercritical fluids and just subcritical fluids exhibit nearly identical chemically and physically desirable characteristics. Further, not all supercritical fluids act as solvents. Helium under some of the conditions found in a typical open tubular column in GC is supercritical but does not act as a solvent. In general, changing from supercritical to a gas or vice versa does not produce useful conditions. Thus, the term

**Figure 3** A plot of diffusion coefficient vs. the reciprocal of temperature at constant density for naphthalene in carbon dioxide. The line denoted  $T_c$  separates the supercritical region on the left from the subcritical (liquid) region on the right. Note that there is no discontinuity when the fluid changes from supercritical to subcritical. The solid lines represent constant densities, from top to bottom of 0.60, 0.70, 0.80, and 0.90 g cm<sup>-3</sup>, even though temperature is changing continuously from left to right. The dashed line indicates a constant pressure line.

supercritical fluid chromatography excludes many of the most desirable chromatographic conditions while including some completely useless conditions.

### Evolution of the Technique

Lovelock originally proposed SFC (he called it 'critical state chromatography') as an inorganic technique using compressed gases such as sulfur dioxide as the mobile phase, although apparently no experiments were performed.

Klesper, called the Father of modern SFC, used short-chain hydrocarbons such as pentane, sometimes modified with dioxane or other polar liquids heated to near 300°C. He and his co-workers reported eluting polymer homologs with molecular weights up to several million. The technique was usually called dense GC. The use of short-chain hydrocarbons at such high temperatures was widely considered to be both impractical and dangerous.

In 1968, Giddings proposed an elutrophic series (a rating of solvents for relative elution strength)

placing dense carbon dioxide beside isopropyl alcohol in solvent strength, based on estimated interaction parameters he used to calculate a Hildebrand solubility parameter. In retrospect, this estimation is clearly far too optimistic. Nevertheless, this series was used for many years, and was one basis for widespread disagreements among practitioners. Since Giddings, carbon dioxide has been the fluid of choice for SFC.

Significant effort was expended during the mid-1980s to extend SFC to the separation of smaller, more polar solutes. However, by the late 1980s there was widespread dissatisfaction with the apparent inability of SFC using pure carbon dioxide to separate more polar solutes. Many other fluids were tried including many chlorofluorocarbons, and fluorocarbons, nitrous oxide, and even xenon with similar poor results. The 'activity' of column packings was generally blamed for this lack of progress, not the (inadequately understood) inherent low polarity of the fluids used as the mobile phase.

Practitioners broke into two camps. One pursued the use of pure carbon dioxide with apparently more inert open tubular columns, while the other experimented with more polar binary and ternary mobile phases and continued to use silica-based packed columns.

Today, packed column SFC is primarily practiced using binary or ternary mobile phases where a polar modifier or co-solvent is added to carbon dioxide. In some cases a third component such as trifluoroacetic acid or dimethylethylamine is also added to the modifier. The solvent strength of pure carbon dioxide is now accepted as somewhat similar to pentane, although the two are probably in different solvent families. In **Figure 4**, Giddings elutrophic series is compared to a modern polarity scale based on the solvatochromic dye (a dye that changes color depending on the 'polarity' of the solvent sheath surrounding it), Nile Red.

## Modifiers

When polar, liquid modifiers are added to the non-polar main fluid they tend to negate the speed advantage of the technique more or less in proportion to the concentration of modifier. If SFC with pure carbon dioxide at a density of  $0.85 \text{ g cm}^{-3}$  is 10 times faster than HPLC, then 20% methanol in carbon dioxide is only five times faster, while 50% methanol is only two times faster.

Fortunately, solvent strength is a highly nonlinear function of modifier concentration. The first small additions of modifier can create very large increases in solvent strength. Methanol is one of the most polar solvents completely miscible with carbon

**Figure 4** Giddings elutrophic series originally presented in a *Science* article in 1968 is replotted on the left, while a solvent strength scale based on the solvatochromic dye, Nile Red, is presented on the right. Note that pure carbon dioxide is much less polar on the Nile Red scale than in Giddings series. Significant concentrations of polar modifier are required (like ~15% methanol) in the Nile Red scale to equal the estimated value in Giddings series. It is now nearly universally accepted that the Giddings estimate was much too optimistic.

dioxide. Using solvatochromic dyes, one can measure the solvent strength of mixtures. The addition of 1% methanol to carbon dioxide increases the apparent solvent strength to 10% of the difference between the two pure solvents, while 10% modifier increases the solvent strength to ~50% of the difference as indicated in **Figure 4** for the binary fluid methanol-carbon dioxide.

This nonlinear relationship means that small additions of modifier cause large increases in solvent strength while retaining much of the speed advantage of SFC over HPLC. The general rule of thumb is that SFC, with modifiers is three to five times faster than HPLC.

The viscosity of binary supercritical and near-critical fluids is also much lower than normal liquids, due, again to a lack of intermolecular forces. The addition of modifier increases viscosity more or less in direct proportion to modifier concentration as shown in **Figure 5**. This low viscosity is helpful in that the pressure drop across a column is as little as 1/10th of that in HPLC, at the same flow rate. Since SFC is three to five times 'faster', the flow rate of the mobile phase must be three to five times higher. Thus, even at the higher flow rate the pressure drop tends to be lower than in HPLC. The lower pressure drop can be exploited for using smaller particle packings or longer columns.

**Figure 5** Pressure drop as a function of modifier concentration. The pressure drop is directly proportional to viscosity. With pure carbon dioxide pressure drop is 9 bar. With pure methanol pressure drop is  $\sim 200$  bar. Flow rate ( $5 \text{ ml min}^{-1}$ ), outlet pressure (125 bar), and temperature ( $35^\circ\text{C}$ ) were all held constant. Column:  $4.6 \times 150 \text{ mm}$ ,  $6 \mu\text{mol l}^{-1}$  BI Cyano. Changing column inlet pressure has a significant impact on the compressibility of the carbon dioxide, which is a function of pressure. Without adequate dynamic compressibility compensation the delivery from the carbon dioxide pump will roll off as the pressure increases (making the total flow and actual composition unknowns).

As a 'rule of thumb', any compound soluble in methanol or a less polar molecule is an ideal candidate for separation by SFC. Any solutes requiring an aqueous or buffered aqueous environment is probably a poor candidate. Peptides are an example of an application where SFC has had little or no impact. On the other hand, lipophilic peptides up to 30 amino acids have been routinely separated. Most small drug-like compounds like those intended for oral administration are ideally suited to SFC. The 'limits' of SFC are poorly defined.

## Where does SFC Fit into Separation Science?

As indicated above, there are two forms of SFC although one is seldom performed today. Open tubular SFC is most often thought of as an extension of GC to heavier, less volatile solutes by replacing some thermal energy with solvation energy. Packed column SFC can be thought of as a subset of HPLC, employing binary and ternary mobile phases and gradient composition programming.

### Open Tubular SFC

Open tubular SFC was relatively popular during the 1980s employing a single pump, usually a large

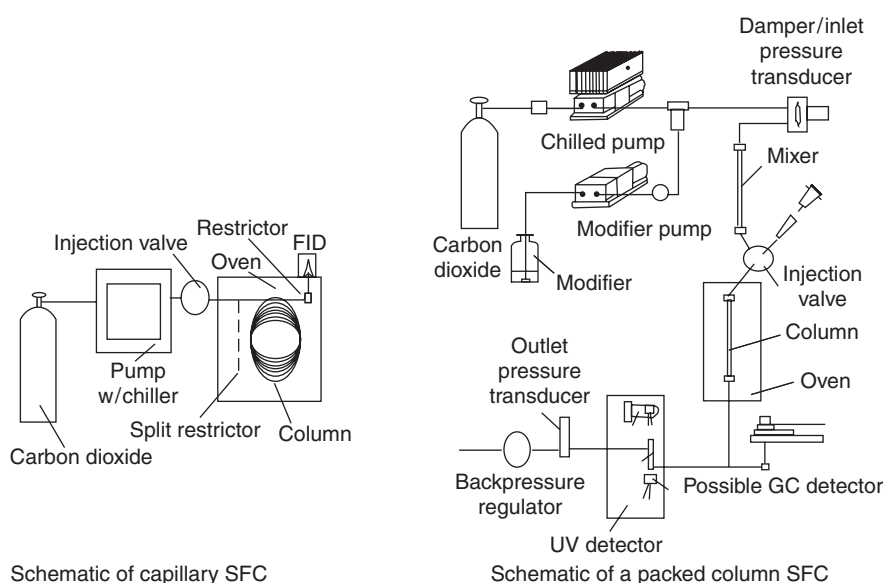

syringe pump, delivering pure fluids, used as a pressure source, and a column oven with a flame ionization detector (FID) (see Figure 6). Columns tended to be  $50 \mu\text{m}$  ID, by 10 m long with thin coatings of bonded stationary phases. Very small volume (i.e., 60 nl), high pressure injection valves were used, sometimes with timed splits to minimize the amount of sample put on-column. Pressures used ranged between 50 and 600 bar, while temperatures tended to be  $70\text{--}200^\circ\text{C}$ . Pressure programming allowed the user to progressively increase the solvating power of the fluid, somewhat analogous to temperature programming in GC. Since pure fluids are all nonpolar, the technique was limited to relatively nonpolar solutes.

Today, few new applications of open tubular SFC are developed and no hardware is manufactured specifically for this use. The general lack of interest in open tubular SFC stems from the inherent low polarity of carbon dioxide, and the lack of other more polar alternatives. There are also performance issues.

Even on the small diameter columns used (i.e.,  $50 \mu\text{m}$ ) diffusion coefficients dictated an optimum linear velocity ( $\mu_{\text{opt}}$ ) in the order of  $0.1 \text{ cm s}^{-1}$ . Since columns tended to be 10 m long, the optimum column hold-up time was in the order of 16.7 min. Since this is unrealistically long for routine analysis, most workers operated up to 10 times  $\mu_{\text{opt}}$ , making the column hold-up time less than 2 min with typical run times of 30 min to 2 h. Efficiency dropped from 200 000 plates near optimum to roughly 20 000 plates at the higher velocity. Very small column diameters made it difficult to make reproducible injections.

The biggest problem with open tubular SFC arose from the use of fixed restrictors to limit the flow of the mobile phase through the column. There are no dynamically adjustable devices capable of controlling the minute flows required in open tubular SFC. 'Integral' restrictors were initially made by heating the end of the fused silica column until it closed, then grinding until an opening of  $1\text{--}2 \mu\text{m}$  was achieved. This end was then inserted into the base of the FID. Obviously, such tiny holes make good filters for the ubiquitous dust particles found throughout chromatographs. As the holes plugged, their flow characteristics changed. 'Frit' restrictors consist of a plug of microporous 'water glass' deposited in the end of a  $50 \mu\text{m}$  tube. The length is trimmed to attain a specific flow. Since there are multiple flow paths, it is more difficult to plug.

All fixed restrictors share a common problem to a greater or lesser degree. As the pressure is programmed from low to high values, the density of the

**Figure 6** Schematic representations of capillary (open tubular) SFC and packed column SFC.

fluid in the column increases, causing the diffusion coefficients of the solutes to decrease. Since the density is typically increased from  $\sim 0.05\text{--}0.75\text{ g cm}^{-3}$ , the diffusion coefficients drop  $\sim 15$  times. To maintain constant efficiency, the linear velocity of the mobile phase should also decrease 15 times in proportion to the density increase. Unfortunately, the mass flow through a fixed restrictor actually increases with the applied pressure. The best fixed restrictors allow a modest increase in linear velocity while the worst cause a major increase. Thus, efficiency changes significantly from the beginning to the end of a pressure program.

Since the initial efficiency is usually degraded by starting at near 10 times optimum, fixed restrictors tend to cause a further ( $\sim 10\text{--}15\times$ ) degradation as pressure is increased. In the analysis of a homologous series, the greatest efficiency is needed near the end of the run where the differences between consecutive members of the series are the least. With fixed restrictors, efficiency is at its worse in this region of the run.

### Packed Column SFC

Modern SFC is much closer to HPLC than GC in that it is performed almost entirely on packed columns and the solvent strength of the mobile phase is varied by adding a polar organic modifier like methanol to the main, nonpolar fluid such as carbon dioxide. Since one fluid is under pressure and the modifier is usually a normal liquid, gradient valves cannot be used. Consequently, packed column SFC requires

more complex hardware (see **Figure 6**), including at least two high pressure pumps. Standard HPLC-like injection valves are used to make injections. A column oven is highly desirable although temperatures are most often controlled in the  $20\text{--}70^\circ\text{C}$  range. Columns are typically  $15\text{--}25\text{ cm}$  long,  $2\text{--}4.6\text{ mm}$  ID (for analytical) with  $3\text{--}6\text{ }\mu\text{m}$  silica-based packings. The most common detector remains the ultraviolet-visible (UV-Vis) light absorbance detector, used in HPLC, with a high pressure flow cell. After the detector, a backpressure regulator controls the column outlet pressure to insure that there is a single phase throughout the chromatographic flow path.

**SFC is normal phase chromatography** Perhaps  $80\text{--}90\%$  of HPLC is 'reversed phase', using aqueous based polar mobile phases and nonpolar stationary phases such as  $\text{C}_{18}$ . The fluid composition is programmed from polar (i.e., pure water) to less polar (more organic). Initially, HPLC was a 'normal phase' technique in which the fluid composition was programmed from less polar (hexane) to more polar (ethanol) during the course of a separation and the stationary phase (silica) was more polar than the mobile phase. Normal phase HPLC has been largely replaced by reversed phase because it is slow, has very slow reequilibration, and tends to have poor reproducibility.

SFC can be viewed as a rebirth of normal phase chromatography with vastly better physical and chemical characteristics. As indicated previously, the optimum flow rate is three to five times higher than even reversed-phase HPLC and reequilibration

is as much as 10 times faster. The last major use of normal phase HPLC is in chiral separations of enantiomers that are mirror images of each other. The separation of enantiomers is a very important aspect of pharmaceutical development. SFC is rapidly replacing normal phase HPLC in this application.

There are a wide range of polar stationary phases available for SFC. They include: bare silica, cyano, amino, diol, ethylpyridine, and many others. Virtually all chiral stationary phase types have been used in SFC.

**Method development** There are three instrumental parameters that affect retention and selectivity: mobile phase composition, pressure, and temperature. Their relative effects are represented schematically in Figure 7. The composition of the mobile phase has the most effect on the retention of polar solutes but tends to have little effect on selectivity. Composition programming is used for gradient elution. Temperature tends to have only a moderate effect on retention but can have a relatively large effect on selectivity. Pressure tends to be a secondary control variable with a moderate effect on retention but little effect on selectivity. The stationary phase affects both retention and selectivity.

**Finding a mobile phase** There is no fundamental principle that makes SFC method development easier to understand than HPLC. On the contrary, there are more variations in SFC, which can be used to further optimize separations. The advantage of SFC lies in its speed and rapid reequilibration after perturbations. Many more experiments can be run per unit time to empirically find the best conditions.

The most common mobile phase is methanol-carbon dioxide. Methanol is the most polar common

solvent completely miscible with carbon dioxide. However, methanol is sometimes too polar with 1% or 2% methanol yielding little or no solute retention. The methanol can be replaced with ethanol or isopropanol or an even longer chain alcohol. One can also change to a different solvent family, similar to HPLC. Acetonitrile is possibly the most common nonalcoholic modifier, but practically any organic solvent can be used.

**Additives** Many highly polar solutes, such as primary aliphatic amines either do not elute or elute with poor peak shapes when binary fluids such as methanol in carbon dioxide are used as the mobile phase. The addition of a third component, usually called an additive to the mobile phase usually dramatically improves peak shapes, as shown in Figure 8 for propranolol. The additive is placed in the modifier and the mixture is pumped as a single fluid. In general, basic solutes require a basic additive and acidic solutes require an acidic additive. Ion pairing (adding an acid to a base or a base to an acid) seldom appears to work. Common additives include

**Figure 7** Schematic representations of the effects of mobile phase composition, pressure, and temperature on retention in packed column SFC using binary fluids. Adjusting composition has the most effect on retention, but, since few of the lines cross, selectivity is only modestly affected. Temperature has little effect on retention but sometimes has a strong influence on selectivity. With binary fluids, pressure is a secondary control variable with modest influence on both retention and selectivity.

**Figure 8** The effect of additive on peak shapes. For solutes that are strong acids and bases, a simple binary mixture of methanol and carbon dioxide may not be polar enough, and peaks tail. Addition of a stronger acid or base as a minor component of the mobile phase often dramatically improves peak shapes as shown for propranolol.

trifluoroacetic acid (TFA) and dimethylethylamine (DMEA).

There appear to be several different possible mechanisms behind suppression of peak tailing but few systematic studies have been published. In general, the polarity limits of SFC remain poorly understood. It appears that the addition of small amounts of water (plus additives) to the methanol significantly increase the polarity of solutes that can be eluted.

The general approach to finding a mobile phase in method development is to quickly try a high concentration (i.e., 40%) of methanol in carbon dioxide. If the peaks emerge with little retention, try a lower concentration until the peaks all elute within a few minutes. The general 'rule of thumb' is that halving modifier concentration doubles retention. It is generally a good idea to not make very large changes in modifier concentration. Each experiment is very fast, so it is often worth the little extra time and effort to make multiple small changes (i.e., 40–20%, then 20–10%). If lowering the modifier concentration fails to yield significant retention, switch to a less polar modifier and repeat the process. If the peaks do not elute or elute with poor peak shapes at high modifier concentration, try an additive in the mobile phase.

**Finding a stationary phase** Finding an appropriate stationary phase is also a trial-and-error process. In general, however, phases similar to the solutes tend to give the best selectivity, giving some indication of where to start. Acids and alcohols tend to have the best selectivity on bare silica and diol phases. Bases tend to give the best separations on amino or ethylpyridine stationary phases. A cyano phase tends to give the least retention of all the polar stationary phases but also tends to yield the poorest selectivity. Similar compounds with different length hydrocarbon chains typically co-elute on all the polar phases. To separate such compounds a hydrocarbon phase, such as C<sub>4</sub>, C<sub>8</sub>, or C<sub>18</sub> may be appropriate.

Many modern packed column SFCs are equipped with a column selection valve and a solvent selection valve. Software 'Wizards' are available that allow simple programming where a large number of different stationary and mobile phases can be automatically tested to find the best conditions without operator intervention.

It is particularly difficult to predict the appropriate stationary phase for chiral separations (where the solutes are chemically identical mirror images of each other). The standard approach is to try a large number and see which of those work.

## Semipreparative SFC

Packed column SFC is scalable even to commercial production of semifinished products. Hardware similar to analytical scale instrumentation can be used with the addition of a device to recover the separated fractions. The recent widespread use of SFC for semipreparative separations has demonstrated several other practical advantages of SFC over HPLC. The fluids remain dense only as long as an external pressure is applied. If that pressure is relieved the fluid rapidly expands to a gas with little or no solvent power.

Separation of polar solutes generally requires polar modifiers like methanol. When the pressure is reduced at the end of the column, the mobile phase breaks down into two phases: one nearly pure carbon dioxide, the other nearly pure methanol. The carbon dioxide phase will be a low density, non-solvating gas, the methanol phase will be a solvating liquid. The polar organic solutes will remain dissolved in the small volume of the liquid phase. Thus, the task of removing the solvent from the collected fractions is greatly reduced.

Other aspects of SFC attracting considerable attention include the very low cost of the main fluid (carbon dioxide), the low disposal costs, and the relatively low toxicity of the fluids used. With large, bulk storage containers carbon dioxide can cost as little as 1/100th the cost of organic solvents.

The carbon dioxide used is recycled and considered 'green' compared to the solvents it replaces. It is generally vented into the atmosphere at the low volumes associated with analytical and semipreparative scale chromatography. At higher flow rates, it can be recycled. The modifier becomes the primary liquid waste stream. Depending on the concentration of modifier used, waste disposal tends to involve less volume and lower toxicity (methanol replaces the acetonitrile) than in HPLC.

## Collecting Fractions

Unlike in HPLC, one simply cannot divert the effluent from the detector into different test tubes or bottles. The fluid volume expands >500 times downstream of the backpressure regulator. The most typical result is the formation of large amounts of aerosol containing the solute molecules. Besides losing up to 70% of the solute, such aerosols can be extremely dangerous. Several devices exist which allow near 100% recovery without exposing anyone to an aerosol.

**Cyclone separator** In the past, the primary device used to collect solute was a cyclone separator. When

a peak was detected, a valve diverted the effluent into a specific cyclone separator. The pressure of the fluid emerging from the detector was reduced until two phases formed. The fluid was then impinged onto the inside wall of a relatively large closed cylinder at an oblique angle. Any liquid (modifier or solute) tends to run down the wall while any gas phase tends to swirl around cyclone-like and exit out the top of the cylinder. The cylinder could be replaced with a cone tapering down to a small hole at the bottom, or consist of a number of connected cylinders, each smaller in diameter than the previous one.

The pressure in a cyclone separator is only slightly lower than the pressure at the end of the column (i.e., 60 or 70 bar versus 100 bar) and the density of the gaseous phase can be relatively high, making it straightforward to recycle the fluid. The use of binary mobile phases make this somewhat more difficult but not impossible.

Cyclone separators work very well in situations where large amounts of the same material need to be purified. For situations where only small amounts of many different solutes need to be purified, they tend to be big and bulky, and require significant time and solvent to clean.

**Berger separator** An alternate phase separator is commercially available that allows small amounts (up to 100 g) to be purified in an automated fashion. It is actually often used to collect fractions when each injection involves a different sample. This approach only functions when binary fluids are used. The pressure is dropped in multiple stages, which initially creates two slow moving phases in intimate contact. This slow movement allows time to add heat. This heat is carefully added to decrease the solubility of carbon dioxide in the modifier. The result is two distinct fluids in equilibrium that are similar in composition to the final fluids at atmospheric pressure. The entire process takes place inside small ID tubing and is self-cleaning. After the fluids are separated, a valve

diverts the two fluids into a collection vessel where the gas phase exits out of the top and the liquid phase drips to the bottom. While it superficially resembles a cyclone separator, the mechanism of phase separation is more complex.

## Introduction

Supercritical fluid chromatography (SFC) has been practiced for more than 40 years and has produced a

remarkable array of applications. Two variants of SFC have emerged. Open tubular SFC almost invariably uses pure fluids, like carbon dioxide, pressure programmed at elevated temperatures and tends to act as an extension of gas chromatography (GC) to heavier, and less volatile materials. Solvation energy is used to partially replace thermal energy to allow such separations at lower temperatures than in

a peak was detected, a valve diverted the effluent into a specific cyclone separator. The pressure of the fluid emerging from the detector was reduced until two phases formed. The fluid was then impinged onto the inside wall of a relatively large closed cylinder at an oblique angle. Any liquid (modifier or solute) tends to run down the wall while any gas phase tends to swirl around cyclone-like and exit out the top of the cylinder. The cylinder could be replaced with a cone tapering down to a small hole at the bottom, or consist of a number of connected cylinders, each smaller in diameter than the previous one.

The pressure in a cyclone separator is only slightly lower than the pressure at the end of the column (i.e., 60 or 70 bar versus 100 bar) and the density of the gaseous phase can be relatively high, making it straightforward to recycle the fluid. The use of binary mobile phases make this somewhat more difficult but not impossible.

Cyclone separators work very well in situations where large amounts of the same material need to be purified. For situations where only small amounts of many different solutes need to be purified, they tend to be big and bulky, and require significant time and solvent to clean.

**Berger separator** An alternate phase separator is commercially available that allows small amounts (up to 100 g) to be purified in an automated fashion. It is actually often used to collect fractions when each injection involves a different sample. This approach only functions when binary fluids are used. The pressure is dropped in multiple stages, which initially creates two slow moving phases in intimate contact. This slow movement allows time to add heat. This heat is carefully added to decrease the solubility of carbon dioxide in the modifier. The result is two distinct fluids in equilibrium that are similar in composition to the final fluids at atmospheric pressure. The entire process takes place inside small ID tubing and is self-cleaning. After the fluids are separated, a valve

diverts the two fluids into a collection vessel where the gas phase exits out of the top and the liquid phase drips to the bottom. While it superficially resembles a cyclone separator, the mechanism of phase separation is more complex.

## Introduction

Supercritical fluid chromatography (SFC) has been practiced for more than 40 years and has produced a

remarkable array of applications. Two variants of SFC have emerged. Open tubular SFC almost invariably uses pure fluids, like carbon dioxide, pressure programmed at elevated temperatures and tends to act as an extension of gas chromatography (GC) to heavier, and less volatile materials. Solvation energy is used to partially replace thermal energy to allow such separations at lower temperatures than in

GC. Today, there are no commercial sources for instruments designed for open tubular columns, although packed column and micropacked column instruments can be adapted for this use.

Packed column SFC tends to use relatively short columns with polar stationary phases, and modified mobile phases at modest temperatures. While packed columns can be used with pure carbon dioxide for many of the same sample types as open tubular columns, the greatest advantages of the technique are in the analysis of small polar molecules using multi-component mobile phases, similar to high-performance liquid chromatography (HPLC). Packed column SFC is a replacement technique for HPLC. Small changes in temperature tend to modify selectivity. Pressure tends to be a secondary control variable, modestly changing retention but having little effect on selectivity.

The best reasons for using packed column SFC stem directly from a few physical and chemical characteristics. From the van Deemter equation it is obvious that the optimum linear velocity of the mobile phase in any chromatographic technique is related to the diffusion coefficient of the solutes in the mobile phase. The diffusion coefficients of solutes in carbon dioxide are up to 10 times higher than in normal liquids, making SFC up to 10 times faster than HPLC. When a modifier is added, this speed advantage is degraded more or less in proportion to the modifier content. Fortunately, solvent strength is a highly nonlinear function of modifier concentration. The first small additions of modifier cause significant increases in polarity.

The viscosity of these fluids is also as little as 1/10th normal liquids, making it possible to make longer columns, pump at higher velocities, or use smaller particles. The fluids are typically compressed gases. When the pressure is dropped, they turn back into a gas, very important in preparative chromatography, since fractions collected will be much smaller (only the modifier plus solute is collected). Finally, SFC using carbon dioxide is considered a 'green' technology since it is recycled and replaces far nastier solvents.

## Historical Development of Application Types

The solvent characteristics of supercritical fluids were recognized more than 100 years ago. Ernst Klesper, a German polymer chemist, published the first paper on SFC in 1961 separating organometallics, after Jim Lovelock suggested the possibility of SFC as an inorganic separation technique,

at an international symposium on GC. Klesper subsequently published a series of papers on polymer analysis using packed columns. The mobile phases he used were often supercritical pentane ( $T > 280^\circ\text{C}$ ) or pentane mixed with a more polar solvent like isopropanol. As the technique evolved, most workers switched away from using such highly flammable hydrocarbons requiring elevated temperatures, toward the use of carbon dioxide or, less commonly, a fluorocarbon refrigerant, or one of a small number of other viable fluids such as nitrous oxide.

Most of the work during the 1980s involved open tubular (capillary) column SFC using pressure programming of pure fluids for the separation of low to moderate polarity, often reactive, homologous series, including heavy hydrocarbons, waxes, natural oils, silicone oils, nonionic surfactants, mono-, di-, and triglycerides, phospholipids, derivatized polysaccharides, isocyanates, and light polymers such as polystyrenes and methacrylates, and many others. The separation of a hydrocarbon boiling point standard is shown in **Figure 1**. Typical run time was an hour.

During this time there was a controversy between open tubular and packed column SFC. There was a widespread belief that carbon dioxide was much more polar than it actually is. Carbon dioxide is roughly as polar as pentane but probably in a different solvent family. Initially, efforts to extend SFC to more polar solutes were limited by the (largely unrecognized) low polarity of carbon dioxide, since there was also a reluctance to abandon the inherent instrumental simplicity of pressure programming a pure fluid.

It was demonstrated that many homologous series could be eluted from an open tubular column, which apparently could not be eluted from the packed column with pure carbon dioxide. The inability to elute polar compounds from packed columns was attributed to excess column activity, not to the low polarity of the mobile phase. Today, we recognize that the open tubular column has perhaps 100 times higher void volume per unit surface area than a typical packed column. This difference in phase ratio makes inherent retention 1/100 as great on the open tubular column, compared to a totally porous column packing with small pores.

The development of binary/ternary mobile phases was foreshadowed by the first of many patents (in 1971) for decaffeination of tea (and later coffee). Caffeine is quite polar with an octanol/water partition coefficient ( $P$ ) more polar than 95% of commercial pharmaceuticals ( $\log P \sim -1$ ). Extraction with pure carbon dioxide was ineffective, but the

**Figure 1** Capillary SFC separation of a simulated distillation standard (Polywax 500) on a  $50\ \mu\text{m} \times 10\ \text{m}$  methylsilicone column; 80–400 bar at  $25\ \text{bar min}^{-1}$  after 5 min initial hold;  $150^\circ\text{C}$ .

extraction yield dramatically improved when water was added.

During the 1980s, work on packed columns was largely ignored but a steady progression of publications showed that mixing more polar solvents with carbon dioxide allowed the elution of much more polar solutes from packed columns than could be eluted from open tubular columns with pure carbon dioxide. Today, almost all packed column SFC applications use binary/ternary mobile phases. Methanol has become the modifier of choice, since it is among the most polar solvents completely miscible with carbon dioxide, is inexpensive, widely available, and of relatively low toxicity. Most organic solvents can be used as the modifier, but most yield less polar mixtures than carbon dioxide/methanol. The polarity range covered by carbon dioxide/methanol mixtures is wider than any binary pair available in HPLC.

For solutes that are strong acids and bases a third component is often required in the mobile phase. In general, acidic solutes require an acidic additive (like trifluoroacetic acid). Basic solutes require a basic additive (like dimethylethylamine). These additives are mixed with the modifier at 0.1–0.5%. Polar solutes are separated on polar stationary phases (silica, amino, diol, cyano, ethyl pyridine, etc.)

It was only in the mid- to late-1980s that it became clear that the speed advantages of SFC over HPLC were best realized using packed columns. Very rapid SFC separations were possible on standard HPLC

**Figure 2** Rapid SFC separation of steroids. Conditions:  $2.0 \times 250\ \text{mm}$ ,  $5\ \mu\text{m}$  Lichrospher silica,  $2.5\ \text{ml min}^{-1}$  of 20% methanol in carbon dioxide at  $70^\circ\text{C}$ , 200 bar. Solutes: progesterone, methyltestosterone, testosterone, estrone, estradiol, cortisone, hydrocortisone, estriol.

columns. For example, the 1989 SFC separation of hydroxysteroids was performed at 10 times the optimum flow rate in HPLC ( $2.5\ \text{ml min}^{-1}$  in SFC versus  $0.25\ \text{ml min}^{-1}$  in HPLC) without apparent degradation of column efficiency, as shown in Figure 2.

A rule of thumb states that any compound soluble in methanol or a less polar solvent is an ideal candidate for SFC. The corollary is that any solute requiring an aqueous medium or a buffered aqueous

**Figure 3** Relative elution of nucleic acids and nucleosides. Conditions: 5 ml min<sup>-1</sup> of 35–80% at 10% min<sup>-1</sup> of (methanol/10% water/0.4% ammonium acetate/0.4% formic acid) in carbon dioxide at 50°C, 200 bar, 4.6 × 200 mm, 5 μm Hypersil Amino. Solutes: uracil, adenine, adenosine cytidine, guanine, cytosine, guanosine dissolved in methanol/formic acid.

medium to dissolve is a poor candidate. Actually, the border between HPLC and SFC remains ill-defined. For example, nucleic acids, particularly guanine, are not soluble in methanol, and actually are not soluble in pure water. Nucleosides are even more problematic but both the acids and nucleosides can be readily separated by SFC with a carbon dioxide/methanol/water/ammonium acetate/formic acid mobile phase, as shown in Figure 3.

Today, most applications are based on packed columns at relatively low temperatures with binary and ternary mobile phases. It has become clear that the characteristics of interest are not limited to ‘supercritical’ conditions. Most packed column applications actually use conditions just below the critical temperature, but well above the critical pressure of the mixed fluids, i.e., subcritical (in other words, ‘liquid’). Unlike many observers’ expectations, important characteristics such as diffusion coefficients and viscosity are virtually identical whether the conditions are just supercritical or just subcritical.

There are two primary application areas of packed column SFC: pharmaceuticals and, to a lesser extent, petroleum. Several other areas such as pesticide analysis and chemicals are practiced but not on a widespread scale. A noncomprehensive list of applications is presented in Table 1.

## Pharmaceuticals

The biggest advances in SFC use have occurred in industrial pharmaceutical labs. Small drug-like

**Table 1** Selected applications of SFC

<i>Pharmaceuticals</i>	<i>Natural products</i>
Chiral separation	Alkaloids glycosides
Rapid method development	Amino acids/nucleic acids
Multiple CSP's in series	Bile acids
Chiral detectors	Sugars-polysaccharides
Enantiomeric excess	Cholesterol
Chiral purification	Steroid hormones
Combi-chem screening	Ecdysteroids
Universal gradients	Digitoxins
Speed vs. purity	Taxol
SFC-MS	Wood resin/rosins
High throughput purification	Fatty acids, prostaglandins
Traditional analytical QA/QC	Mono-, di-, and tri-glycerols/
Quantification	glycerides
Purity	Phospholipids
Excipients	Ubiquinones
Fermentation extracts	Terpenes
ADME	Lactones
Metabolites in biological	Favonoids
SFC-MS of metabolites	Carotenoids
Antidepressants	Fat and water soluble vitamins
Antipsychotics	Essential oils
Stimulants	Waxes
<i>Herbicides and pesticides</i>	<i>Chemicals</i>
Sulfonylurea pesticides	Surfactants
Phenylurea pesticides	Isocyanates
Carbamates	Silicone oils
Organochlorine	Polymers
Organophosphorus	Polymer additives
Triazine herbicides	Epoxy resins
Pyrethrins/pyrethroids	<i>Petroleum</i>
<i>Environmental</i>	Aromatics in diesel
Phenols	Olefins in gasoline
Phthalates	Simulated distillation
PAHs	
PCBs	

molecules are ideal candidates for SFC. Most commercial drugs are neither too ‘polar’ nor too ‘lipophylic’. The former would be eliminated from the body too rapidly through the urinary tract. The latter are trapped in body fat and can actually become toxic. Pharmaceuticals taken orally have an average log *P* of 2.5–3. Compounds with log *P* < 0 (such as most proteins) tend to be administered by injection, which is considered undesirable. Those with log *P* > 5 tend to be toxic. Compounds shown to have been eluted by SFC have log *P* values between –1 and 7. Thus, SFC appears to be the perfect match for small drug-like molecules intended for oral administration. There is an extensive literature, including thousands of papers, on the SFC separation of the most common orally administered pharmaceuticals.

## Chiral Separations

Fundamentally, packed column SFC is a replacement technique for normal phase HPLC (n-HPLC). The most obvious application demonstrating the superiority of SFC is in chiral analysis and purification. Chemically, chiral molecules are identical mirror images of each other. They can only be separated by differences in shape.

SFC uses the same stationary phases as HPLC. Selectivity is similar but not identical. One of the greatest differences from n-HPLC is in speed. SFC optimum flow is inherently three to five times faster, while peak shapes are often significantly better. Unlike n-HPLC, SFC reequilibrates after passage of only a few column volumes. Overall, SFC is often much more than 10 times faster than HPLC. A fast chiral SFC separation is shown in **Figure 4**. Note that the column is not 'high speed' but a standard  $4.6 \times 250$  mm column with  $10\text{ }\mu\text{m}$  particles. Some industrial pharmaceutical companies have dropped HPLC for chiral analysis and use SFC for less polar solutes, and high-performance capillary electrophoresis (HPCE) for water-soluble solutes. Unlike HPCE, SFC is scalable.

The mobile phase used in SFC costs as little as 1/20th HPLC solvents for the same work. In semipreparative applications, the absolute cost savings can be dramatic. In SFC, a 20–21.2 mm ID column can cost as little as  $\$0.46\text{ h}^{-1}$  (more typically  $\$3\text{ h}^{-1}$ ) while the solvent cost on the same column in HPLC can be as much as  $\$27\text{ h}^{-1}$ . Since the SFC performs three to 10 times more work in the same time, the cost per unit of work is dramatically better. Further, sample dry down is substantially easier since the carbon dioxide flashes away when the pressure drops, leaving behind the fractions in much smaller volumes of the modifier. Finally, waste generation is also reduced. Several organizations have claimed a single semipreparative SFC running 21.2 mm ID

columns overall saves up to  $\$1\,000\,000\text{ year}^{-1}$  associated with solvent purchase, dry down, and disposal.

## Supporting Combi-Chem

For the last 5–10 years, combinatorial chemistry has been the method of choice for developing huge numbers of small drug-like compounds that can be tested for biological activity by high throughput screening (HTS). Small groups are often presented with the task of synthesizing, analyzing, purifying, and registering 40 000 compounds per year or more. The consensus opinion has shifted over time to indicate that relatively pure compounds should be tested by HTS to avoid false positives and negatives. Although synthesis can be optimized to create relatively pure compounds, it is more typical to produce larger numbers of relatively dirty compounds, requiring both high throughput analysis and purification.

Most practitioners perform a version of triage on the samples. The intent is to eliminate from consideration all the samples where the desired compound is not found, where there is not enough substance to purify, or where there are large numbers of potentially interfering contaminant peaks present. HPLC with mass spectrometric detection (HPLC–MS) is used for analysis, followed by semipreparative HPLC for purification. The mass spectrometer verifies that the compound of interest is present. Other detectors are used to attempt to quantitate how much is present. After the analytical step, the samples that have been approved are purified. In some cases, the peaks are collected based on triggering by another mass spectrometer on the preparative instrument. In other cases, the retention time of the peak of interest in the analytical run is translated or scaled to the preparative unit, and the peak collection occurs in time windows or by UV triggering. HPLC tends to use large amounts of toxic organic solvents like acetonitrile, which becomes toxic waste. Fractions are water/acetonitrile mixtures, which require extensive lyophilization to remove from the solutes.

Since SFC is three to five times faster, for the same work output, SFC is becoming an attractive alternative to HPLC for both analysis and purification. SFC is 'normal phase', and the elution order is generally opposite to reversed-phase HPLC (RPLC). Thus, SFC purification makes most sense following SFC analysis. The same general approach is followed, using SFC–MS, to identify which samples should be purified by SFC. The tendency has been to use SFC to achieve higher resolution in the same time compared to HPLC, rather than increase the number of samples per unit time. A single preparative

**Figure 4** Chiral separation of *t*-stilbene oxide, on a  $4.6 \times 250$  mm,  $10\text{ }\mu\text{m}$  Chirapack AD column using  $5\text{ ml min}^{-1}$  of 40% methanol in carbon dioxide. Outlet pressure was 100 bar, temperature was  $35^\circ\text{C}$ .

instrument is theoretically capable of more than 100 000 purifications of up to 100 mg each per year.

As in chiral purification, the mobile phase is dramatically cheaper than in HPLC. Less toxic waste is generated, and much less power is required to dry down samples. One of the biggest advantages of SFC is actually in the postpurification sample handling. The fractions tend to be much smaller and are 100% organic, allowing much faster, much easier, much cheaper dry-down.

### Natural Products

Packed column SFC has been used extensively to analyze natural products. Fat-soluble compounds like squalene, vitamins A, D, K and E, carotenoids, ubiquinones, cholesterol, mono-, di-, and triglycerides, and fatty acids have all been extensively studied. Hydroxy fatty acids, prostaglandins, and phospholipids have also been separated. Omega-3-fatty acids are separated out of fish oil on a commercial scale by packed column SFC.

Polar derivatives of cholesterol, such as keto and hydroxy steroids, bile acids, and ecdysteroids have all been extensively studied.

Nonvolatile terpenes, including alcohols and acids, wood resins, lactones, bittering acids from hops, etc., have been analyzed. Many alkaloids, and glycosides, toxins, and stimulants have been extracted and chromatographed. Compounds like caffeine, theophylline, and theobromine (see Figure 5), taxol, digitalis glycosides, reserpine, ginkgosides, garlic and onion extracts, and 'loco weed' extracts. Sugars,

polysaccharides, and glycosides have been eluted with an evaporative light scattering detector (ELSD), or a mass spectrometer.

Both native and derivatized amino acids are readily eluted. Most low polarity peptides containing up to perhaps 30 amino acids and small cyclic peptides are easy to elute. A carbon dioxide/methanol/water/formic acid mobile phase can also elute many 'water-soluble' vitamins.

### Petroleum

#### Aromatics in Diesel

There are two American Society of Testing Materials (ASTM) methods based on SFC that have major implications in environmental health.

Most industrial countries have set as a goal a major reduction in the aromatic content in diesel fuel to cut down on particulates emissions. Traditional methods such as fluorescence indicator analysis are slow and require significant solvent but more importantly have difficulty quantitating low levels of aromatics.

The aromatic content in diesel fuel (ASTM Method #5186) is a group separation method where a bare silica column elutes all aliphatic hydrocarbons as a single peak, olefins as a second nearly resolved single peak, and a series of largely resolved peaks each representing a set of ring compounds, as shown in Figure 6. The first such peak contains compounds with a single ring, the next peak contains compounds with two rings, etc. All compounds respond in a

**Figure 5** SFC analysis of caffeine analogs: 0.5  $\mu$ l neat injection onto a 4.6  $\times$  250 mm, 5  $\mu$ m Lichrospher silica column with 2.5 ml min<sup>-1</sup>, of 8% methanol in carbon dioxide at 30°C, 250 bar.

**Figure 6** Aromatic content of diesel fuel with indication of ring number. Relative area under the FID trace is used to quantitate the different groups.  $4.6 \times 250$  mm,  $5 \mu\text{m}$  Lichrospher silica,  $2.5 \text{ ml min}^{-1}$  pure carbon dioxide,  $27^\circ\text{C}$ , 140 bar.

flame ionization detector (FID), which is used for quantitation. A UV detector is also sometimes used.

The method requires a resolution of four between  $\text{C}_{16}$  (or  $\text{C}_{22}$ ) and toluene. In reality it is relatively trivial to achieve resolutions up to 14 on some silicas. However, other silicas do not separate this standard at all.

### Olefins in Gasoline

Recently, the group separation method has been extended to further resolve the olefins from the aliphatic hydrocarbons, particularly in gasoline. A silver column is placed in series with the silica column and is switched in and out of line. Olefins are strongly retained on the silver column while the aliphatics are not. After the olefins are trapped on-column, the flow is switched, so the aromatics are diverted directly into the FID. Later, flow is switched again and the olefins are back-flushed off the column into the detector.

### High-Temperature Simulated Distillation

A still may take 15–24 h to adequately characterize a crude oil sample by manually or automatically recording the weight loss of the sample versus temperature over time. Stills have been ‘simulated’ using a temperature programmed GC method that reaches  $450^\circ\text{C}$  and only takes 70 min.

There are several problems with the GC method. A fraction ( $\sim 0$ –5%) of some crude oils is not volatile and is deposited on the head of the column, changing the column characteristics. Depending on the concentration of this nonvolatile material, the user may need to cut 10–20 cm off the front of the column after 1–10 injections. It is generally accepted that this

contamination and manual manipulation results in an average column lifetime of no more than 100 injections. In the extreme, a single injection can ‘kill’ a column. Further, there is some controversy over the consequences of using  $450^\circ\text{C}$  as the injection port and column temperatures. One camp suggests that some compounds will break down into smaller pieces when they hit these high temperatures, distorting the mass distribution (which affects the value of the oil). Others dismiss such concerns as overly conservative.

In SFC, a pressure program from 70 to 400 bar, at a temperature of  $150^\circ\text{C}$  provides an alternative to the GC method. The sample, injection valve, and transfer line must all be heated. A methyl packed column performs with selectivity similar to a methyl silicone GC column. Components with boiling points greater than  $\text{C}_{130}$  have been eluted.

The solvating power of the dense carbon dioxide replaces most of the thermal energy of the high temperature in the GC method. The sample (including the nonvolatile part) is soluble in carbon dioxide. There is a simple test that corrects for the nonvolatile component. Since the nonvolatile components do not accumulate, a single packed column has been used for as many as 4000 analyses without serious degradation, dramatically improving column life. The data have been shown to be equivalent to that obtained by the GC method.

## Other Applications

### Agricultural Chemicals/Environmental Analysis

Packed column SFC has been shown to be widely applicable in the analysis of agricultural chemicals and in environmental analysis but has not achieved widespread use.

SFC can rapidly separate many of the thermally labile pesticide families such as sulfonylurea, phenylurea, and carbamate pesticides in addition to organochlorine, organophosphorus, and triazines. All these tolerate modified fluids and polar columns operated at modest temperatures. The carbamates are an example of thermally labile pesticides usually separated by HPLC. A rapid isocratic separation is presented in Figure 7.

Pesticides and herbicides have been trapped out of water and detected with various GC-like detectors such as the nitrogen phosphorus detector and the electron capture detector as well as UV photodiode array spectra. SFC is fully compatible with mass spectrometry and many other GC and HPLC detectors.

**Figure 7** Separation of carbamate pesticides on a  $4.6 \times 250$  mm,  $5 \mu\text{mol l}^{-1}$  Lichrospher Diol column with  $2.5 \text{ ml min}^{-1}$  of 5% methanol in carbon dioxide at  $30^\circ\text{C}$ , 200 bar;  $2 \mu\text{l}$  of  $2 \text{ mg ml}^{-1}$  each.

Polycyclic aromatic hydrocarbons, polychlorinated biphenyls, phenols, and phthalates have all been separated rapidly and effectively.

### Polymers and Homologous Series

**Silicone oils** Polysiloxanes (silicone oils) are widely used in industrial products. They consist of homologous series. The mass distribution in a sample dictates its physical properties, such as viscosity. The simplest member, dimethylpolysiloxane has a repeating unit of  $\text{H}_3\text{C}-\text{SiO}-\text{CH}_3$ , with a molecular weight of 74. There are now packed column separations (at  $150^\circ\text{C}$ ) that show individual maxima for more than 160 such units, suggesting a maximum molecular weight approaching  $\sim 15\,000$ . Heavier components can be eluted but the chemical differences between consecutive homologs are too small to result in individual maxima. There are often subseries of peaks offset from the main series that give some insight into the reaction mechanism or pathways.

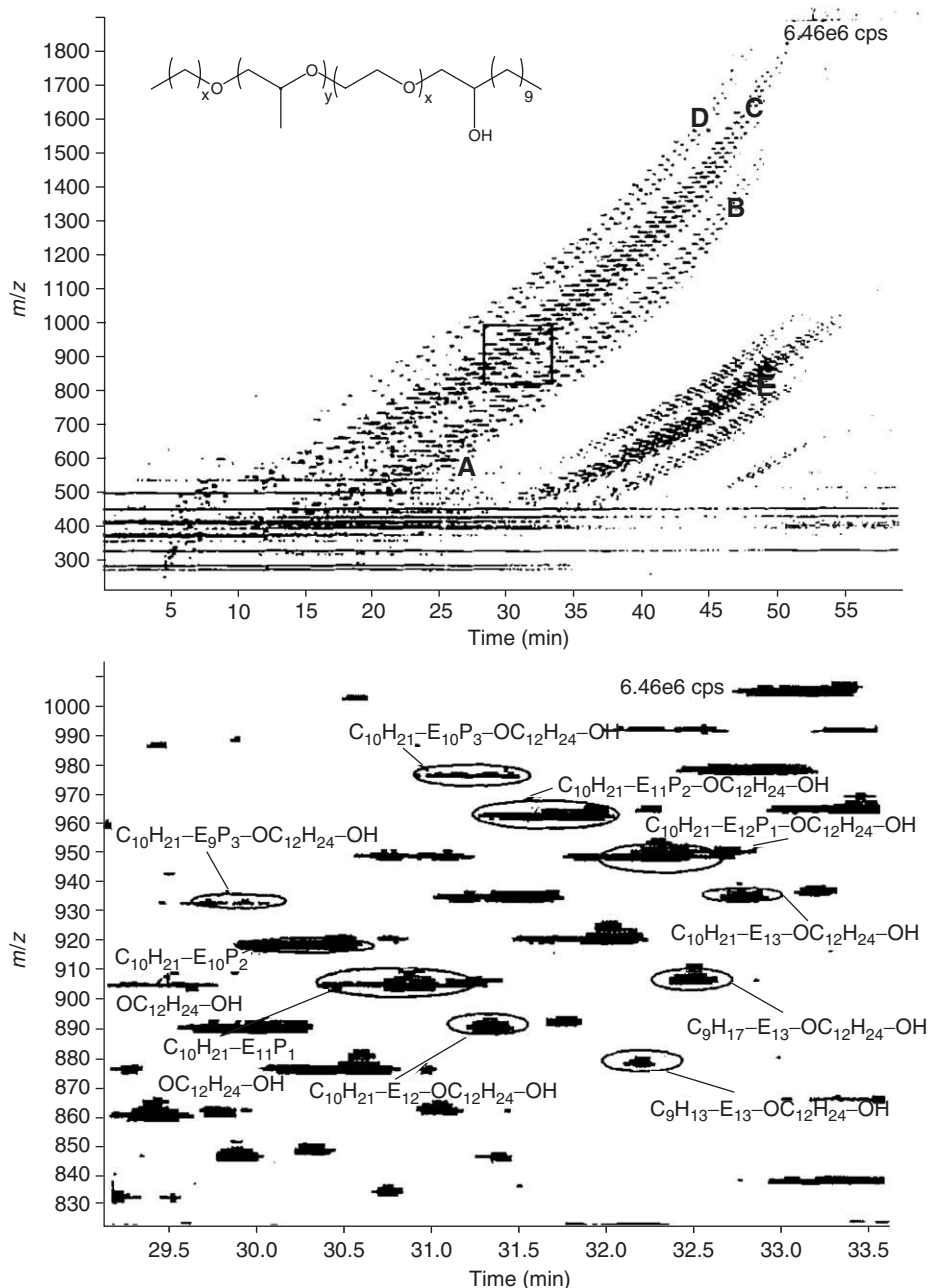

Although carbon dioxide is often described as similar in polarity to pentane or hexane, the addition of 10% hexane to carbon dioxide significantly increases the maximum molecular weight to between 25 000 and 40 000 that can be eluted. This should not be surprising. Some of Klesper's early work used pentane and modified pentane at  $260^\circ\text{C}$  to elute certain polymers with molecular weights up to several million.

All older chromatograms of silicone oil were collected using an open tubular column with an FID as detector. More recently, it has been shown that carbon dioxide is completely transparent to below 190 nm in the UV. All the siloxanes absorb light below 195 nm. Since packed columns allow larger, more reproducible injection volumes, and UV detectors do not need fixed restrictors, the method of choice appears to be packed columns with UV detection at 190 nm.

**Nonionic surfactants** Ethoxylates and propoxylates are widely used in liquid detergents. They contain a fatty acid tail and an ethyl-oxy or propyl-oxy repeating unit and are often terminated with a hydroxyl group. Each repeating unit produces a major set of peaks but for each repeating unit there is a subset of peaks representing the various chain length fatty acids.

These compounds are modestly polar but can be eluted with pure carbon dioxide from either an open tubular or packed column. Peak shapes are modestly improved by derivatizing the terminal hydroxyl group. As with the silicone oils, these compounds absorb UV at 190 nm.

Pinkston published several of the most incredible chromatograms ever (see Further reading). He made a long packed column to maximize chromatographic resolution then combined it with a mass spectrometer. The resulting two-dimensional contour plots reveal thousands of isomers in some of these samples. An example is shown in Figure 8. Such a

**Figure 8** Top: A contour plot of a low molecular weight alkoxyated polymer with mass on the y-axis and retention time on the x-axis. Each 'dot' represents a different component in the mixture. chromatogram yields minute details about the reaction mechanism.

## Future Perspectives

In the year or so during which this summary of applications was written there has been a significant

increase in the number of SFC users although the specific applications remain the same. The general population of HPLC users is beginning to realize that SFC is actually a subset of HPLC with enhanced fluid characteristics and an environmentally more friendly fluid that offers dramatic decreases in solvent cost. While the primary uses remain chiral separations in

pharmaceuticals and group separations in petroleum, the inherent superiority of the fluids is being recognized more generally and the technique is being more generally applied, particularly with pharmaceuticals. The biggest driver is at the semipreparative scale where the higher throughput and dramatic decrease in costs seems to be rewriting the cost model for chromatography as an industrial process.

## Introduction

A surface can be defined as any interface between two components of a system with different compositions or properties. The simplest example is the interface between materials of two different phases, i.e., a solid and a gas, a liquid and a gas, or a

solid and a liquid. However, the interface between two different solids or two immiscible liquids is also a surface. In strict terms, such interfaces comprise two surfaces (e.g., at the interface between a solid and a liquid, one can refer to the surface of the solid and the surface of the liquid as separate entities). The interface between a solid or liquid and a vacuum is, in contrast, a single surface.

In purely geometric terms, a surface has no intrinsic thickness, but in practical terms a surface must comprise one or more layers of atoms or molecules. When dealing with the properties of solids and liquids, the surface and interior are usually considered separately. This is partly because, for any material of significant mass and volume, the number of atoms at the surface is negligible compared to the number of internal atoms. Mostly, however, it reflects the fact that the mathematical treatment of ordered substances is simplified if the structural periodicity is assumed to be infinite. The important point, and the reason that surface analysis is of interest at all, is that the surface differs in its properties from the bulk (internal) material even though it is made of exactly the same atoms. This is because atoms at the surface are relaxed, i.e., not all the bonds are constrained by interactions with neighboring atoms in the same material. Relaxed atoms have free bonds that are available to interact with atoms and molecules on the surface of the adjacent phase, such as the gas or liquid surrounding a crystalline solid.

The properties of surfaces have always been important to humans, from the development of the first stone tools through to the microprocessors and digital media of the present day. However, the analysis of surfaces did not become a mainstream scientific discipline until the 1960s, when it became possible to achieve ultrahigh vacuum on a routine basis. The ability to generate ultrahigh vacuum (generally defined as  $10^{-7}$ – $10^{-8}$  Pa) brought about a revolution in surface analysis for two reasons. First, it became possible to prepare atomically clean surfaces and maintain them in a contamination-free state over a typical experimental period. Under high vacuum or even very high vacuum conditions (down to  $10^{-6}$  Pa), the number of gas-phase molecules is sufficient to generate a monolayer of contaminants on the surface by molecular collision in a matter of seconds, particularly if the surface is reactive. In contrast, under ultrahigh vacuum, a full monolayer takes up to 1 h to form. Second, ultrahigh vacuum conditions allow low-energy electron and ion-based analytical methods to be used without interference from gas-phase scattering. These methods are discussed briefly below, and in more detail in the subsequent articles.

## Techniques for Surface Analysis

Almost all of the techniques currently used for surface analysis are based on interactions between the surface and incident photons, electrons, or particles (summarized in Table 1). At the simplest level, a surface can be examined visually, with either the naked eye or using a microscope. Where higher resolution is required, scanning electron microscopy can be used to show the detailed structure or morphology of a surface down to a resolution of  $\sim 2$  nm, with the added advantage of a large depth of field. This involves the use of a finely focused beam of high-energy, raster electrons (energy of tens of thousands of electron volts) that releases low-energy electrons from the surface, which can be detected and interpreted as an image. Other useful methods include scanning tunneling microscopy and atomic force microscopy, each of which can be used under normal atmospheric conditions although experiments are often carried out under vacuum so that the results can be compared with those obtained from spectroscopy. In each technique, a tip travels across the surface of the analyte and the deflection is measured generating a topological map of the surface at near atomic resolution. In the case of scanning tunneling microscopy, both the tip and the surface are conducting. The tip is not in direct contact with the surface and a tunneling current is measured between the surface and the tip. Atomic force microscopy can be used to analyze nonconducting surfaces. The tip can be constantly in contact with the surface, it can oscillate at high frequency, and tap the surface with a specific periodicity, or it can scan a few tenths of a nanometer above the surface. Additionally, the probe tip can be coated with a magnetic substance allowing the magnetic fields immediately above the surface to be measured.

The arrangement of atoms on a surface can be probed by various spectroscopy techniques. Some techniques make use of electron diffraction, where the electron energy can range from a few volts to many thousands. These methods have been the mainstay of surface analysis for many years, particularly for the detection of surface structures on single crystal faces. The area of analysis depends on the electron beam diameter and the interference length, and this usually means that the area from which the signal originates is  $\sim 1$  mm<sup>2</sup> with low-energy beams. Other methods use a beam of ions to strike the surface and displace atoms, which can be ionized and detected by mass spectrometry. Yet other methods involve bombarding the surface with electrons or X-rays, and then measuring the photons that are emitted. Depending on the technique, only the true surface

**Table 1** Overview of surface analysis techniques

<i>Technique</i>	<i>Principles and applications</i>	<i>Variations</i>
<i>Electron spectroscopy techniques</i>		
Appearance potential spectroscopy (APS)	A group of techniques in which the energy of the excitation beam (X-rays, electrons) gradually increases, allowing the onset of excitation at a core level to be detected	Auger electron appearance potential spectroscopy (AEAPS) Soft X-ray appearance potential spectroscopy (SXAPS) Disappearance potential spectroscopy (DAPS)
Auger electron spectroscopy (AES)	The sample is bombarded with an electron beam, leading to the ejection of core electrons from the analyte atoms. The resulting vacancies are filled by other electrons falling from higher levels, and their energy is transferred to so-called Auger electrons, which leave the atom with a specific kinetic energy. AES identifies elemental compositions of surfaces by measuring the kinetic energies of Auger electrons. Widely used for the analysis of surfaces and thin films	X-ray induced Auger electron spectroscopy (XAES) Auger photoelectron coincidence spectroscopy (APECS) Scanning Auger microscopy (SAM)
Electron energy loss spectroscopy (EELS)	The sample is bombarded with a monoenergetic beam of electrons. The inelastic scattering of low-energy electrons is used to measure vibrational spectra of surface species, allowing elemental characterization. Often used in concert with electron microscopy	High-resolution electron energy loss spectroscopy (HREELS) Spin polarized electron energy loss spectroscopy (SPEELS)
Electron momentum spectroscopy (EMS) (also known as (e,2e) spectroscopy)	The surface of the analyte is bombarded with an electron beam, causing incoming electrons to be scattered and resident electrons to be ejected. The scattered and ejected electrons are detected simultaneously	
Extended X-ray absorption fine structure (EXAFS)	The sample is targeted with a monochromatic X-ray beam and the photon energy is gradually increased until it exceeds the absorption edge of one of the components of the analyte. This results in a large increase in absorption and the resulting photoelectrons are backscattered by the atoms surrounding the emitting atom	Near edge X-ray absorption fine structure (NEXAFS) (also known as X-ray absorption near edge structure (XANES)) Surface extended X-ray absorption fine structure (SEXAFS)
Infrared spectroscopy	A group of techniques using infrared irradiation to study molecules vibrating on a surface. Vibrating molecules with a significant dipole moment will absorb infrared light at specific frequencies depending on the molecular species. Infrared spectra therefore show absorption peaks that are characteristic of particular molecules and the way they are bonded to the surface	Transmission infrared spectroscopy (TIRS) Diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) Reflection–absorption infrared spectroscopy (RAIRS) (also known as infrared reflection absorption spectroscopy, IRAS or IRRAS) Multiple internal reflection spectroscopy (MIR) Attenuated total reflectance (ATR) Surface enhanced Raman scattering (SERS)
X-ray photoelectron spectroscopy (XPS) (also known as electron spectroscopy for chemical analysis, ESCA)	The sample is bombarded with X-rays, leading to the emission of photoelectrons. The kinetic energy of the excited photoelectrons depends on the energy of the incident X-ray (generally in the range 200–2000 eV) minus the binding energy of core level electrons, which are specific for each element. XPS is used for the quantitative compositional analysis of surfaces	Spin polarized X-ray photoelectron spectroscopy (SPXPS)

Table 1 Continued

<i>Technique</i>	<i>Principles and applications</i>	<i>Variations</i>
Ultraviolet photoelectron spectroscopy (UPS)	Similar in principle to XPS, but the sample is irradiated with vacuum ultraviolet radiation (10–45 eV) which is only capable of ionizing electrons from the outermost (valence) levels of atoms. Typically used to determine the electronic structure of solids and the adsorption of relatively simple molecules on metals	Angle resolved ultraviolet photoelectron spectroscopy (ARUPS) also known as angle resolved photoelectron spectroscopy (ARPES) Spin polarized ultraviolet photoelectron spectroscopy (SPUPUS)
Inverse photoemission spectroscopy (IPES) also known as Bremsstrahlung isochromat spectroscopy (BIS)	The sample is targeted with a beam of electrons and the light emission is measured, providing information on the empty density of states above the Fermi level	K-resolved inverse photoemission spectroscopy (KRIPES) Spin polarized inverse photoemission spectroscopy (SPIPES)
<i>Electron diffraction techniques</i>		
X-ray photoelectron diffraction (XPD)	Similar in principle to XPS, but involving the analysis of crystal surfaces. Under these circumstances, emitted photoelectrons may experience diffraction effects, which help to determine the crystal structure in the vicinity of the emitting atoms	
Auger electron diffraction (AED)	Similar in principle to AES, but involving the analysis of crystal surfaces. Under these circumstances, emitted Auger electrons may experience diffraction effects, which help to determine the crystal structure in the vicinity of the emitting atoms	
Low-energy electron diffraction (LEED)	Bombardment with electron beam in the 20–1000 eV range. Emerging diffracted beams are accelerated onto a phosphorous screen. Used to control the surface quality of a sample prepared under UHV conditions	Reflection high energy electron diffraction (RHEED)
<i>Ion emission techniques</i>		
Secondary ion mass spectrometry (SIMS)	Bombardment of a sample surface with a primary ion beam followed by mass spectrometry of the emitted secondary ions. Used for the analysis of trace elements in solid materials, continuous erosion by ion beam allows depth analysis	Secondary/sputtered neutral mass spectrometry (SNMS)
Ion scattering spectroscopy (ISS)	The sample surface is bombarded with a beam of ions. A certain number will undergo elastic reflection and the intensity and emission angle of these scattered ions provides structural information about the surface	Low-energy ion spectroscopy (LEIS) Medium-energy ion spectroscopy (MEIS) High-energy ion spectroscopy (HEIS) Rutherford backscattering (RBS)
Temperature-programmed techniques	The sample is heated in a vacuum and the residual gas is detected using a mass analyzer. As the temperature rises, certain absorbed species will have enough energy to desorb and will be detected	Temperature-programmed desorption (TPD) also known as thermal desorption spectroscopy (TDS) Temperature-programmed reaction spectroscopy (TPRS)
<i>Microscopy</i>		
Light microscopy (LM)	Low-resolution visual analysis of surfaces	
Electron microscopy (EM)	High-resolution analysis of surfaces using high-energy electrons that cause resident electrons to be ejected. When these are detected, they can be converted into an image	Scanning electron microscopy (SEM) Transmission electron microscopy (TEM) Scanning transmission electron microscopy (STEM) Scanning Auger microscopy (SAM)

Continued

Table 1 Continued

Technique	Principles and applications	Variations
Field ion microscopy (FIM)	The specimen is formed into a sharp tip to which a positive potential is applied. The tip is surrounded by inert gas atoms, which are drawn towards it. As they strike, electrons tunnel into the tip leaving the gas atoms ionized. The ions then accelerate away and can be detected as spots on a screen, corresponding to atoms at the tip surface	Atomic probe field ion microscopy (APFIM)
Scanning probe microscopy (SPM)	Techniques in which a surface is imaged at high (and in some cases atomic) resolution moving a probe across it, either in direct contact or just above the surface	Atomic force microscopy (AFM) Ballistic electron emission microscopy (BEEM) Chemical force microscopy (CFM) Lateral force microscopy (LFM) Magnetic force microscopy (MFM) Near-field scanning optical microscopy (NSOM) Scanning tunneling microscopy (STM)

may be analyzed (the uppermost layer of atoms or molecules) or the probe may penetrate up to several micrometers into the bulk material.

Many of the available surface analysis techniques are described in more detail in **Table 1**. The large number of techniques sometimes makes it difficult to determine which would be the most suitable for the analysis of particular materials. Often, the choice is made based on empirical knowledge, but in many cases individual researchers stick to the methods they understand the best and work with most of the time. Depending on the chemical composition and physical properties of a surface, many or only a few of the available analytical techniques might provide useful information. Several methods are often used in parallel to derive the maximum amount of information from a particular surface.

## Contamination and Decontamination

There are many reasons for studying and characterizing surfaces, and the applications of surface analysis cover a wide range of basic science disciplines, industrial applications, and manufacturing processes. Surface analysis is usually carried out to obtain information about the chemical composition of a surface, the concentration of trace impurities, the physical structure, or alterations that occur when surfaces are contaminated, stressed, or subjected to different types of modification. Such information is useful to researchers or manufacturers because they must understand the behavior of the materials they are working with in order to verify theories or make better products and procedures.

Contamination on the surface of the sample may represent the 'target' of the analytical procedure. One case in point is the use of surface analysis to verify cleaning procedures. For example, it would be helpful to know if a cleaning procedure used to remove environmental contaminants (e.g., organic depositions from vehicle exhaust fumes on buildings) also caused damage to the underlying material that should be preserved. It would also be helpful to know whether a cleaning procedure used to remove a harmful contaminant was in fact exchanging that contaminant for another surface species that could have similarly hazardous properties. Contamination often affects the surface of a material more than the bulk, even in materials with a stated purity level in excess of 99.99%. Polycrystalline metals, for example, often have impurities that segregate at grain boundaries.

In other cases, contamination on the surface of the sample is undesirable, and detracts from the analytical procedure. Almost all surfaces exposed to the atmosphere have an adventitious overlayer containing organic carbon and oxygen, even where precautions have been taken in specimen handling. While many of the analytical techniques used to investigate surfaces allow *in situ* cleaning after sample loading, it is still a good idea to clean the sample prior to analysis. Careless handling, including contact with fingers or storage in nonclean environments, often results in the formation of a surface layer that completely masks the underlying substrate. The contamination resulting from careless handling can also have deleterious effects on many surface analysis systems.

The modification of surfaces, even those normally considered to be inert, caused by atmospheric exposure can also result from reactions involving simple gases. Many metals, alloys and even polymers possess a very thin surface layer of oxide or hydroxide because of reactions with oxygen and/or water. Carbon monoxide also reacts with these substrates, so the consequences of such interactions must be taken into account when interpreting experimental data. Various cleanup strategies can be employed to overcome such problems, including sputtering (ion bombardment), heating, or chemical reduction, but this depends on the composition of the analyte. While heating will often desorb surface contaminants, many samples cannot withstand the high temperatures. Ion bombardment and chemical reduction can sometimes modify the surface chemistry of the sample in an undesirable way, i.e., the procedures are destructive. This also applies to routine analysis methods using ion bombardment, e.g., secondary ion mass spectrometry, although the destructive effects can be limited by maintaining a low ion current. Electron beam methods such as scanning electron microscopy and Auger electron spectroscopy can alter some samples as a result of interactions with the probe electron beam. Other approaches such as X-ray photoelectron spectroscopy and infrared reflection absorption spectroscopy usually do not alter the specimen.

## Information Derived from Surface Analysis

Although many of the techniques described in Table 1 can be used to obtain chemical and elemental information about surfaces, the data are in some cases restricted to particular chemical groups and moieties, while in other cases particular elements cannot be detected. For example, Auger electron spectroscopy and X-ray photoelectron spectroscopy cannot detect hydrogen directly, and only in a few instances can the presence of hydrogen be inferred from spectral features. Both techniques exploit the fact that electrons ejected from atoms in solids will not retain their characteristic quantized energy in collisions with bulk atoms. Thus, the observed signals come only from atoms in the first few layers of the solid. With techniques that depend on the emission of electrons, photons, or ejected material, the analyst must be vigilant of possible overlapping signals from unexpected species. Techniques such as ion scattering spectroscopy, which measures the energy reflected from a surface irradiated with an incident ion beam (usually  $\sim 1$  keV), are not able to discriminate between elements with similar properties, i.e., they

cannot distinguish small changes in atomic number or atomic weight.

Estimates of the relative amounts of the elemental and chemical surface species are often very important, so the detection level required for a given probe must be considered. Occasionally, surface sensitivity in the parts per million regime is needed and a technique such as secondary ion mass spectrometry would be the most appropriate. In this approach, a beam of energetic ions is used to eject material from the specimen surface for analysis by mass spectrometry. Where a lower sensitivity is acceptable, such as when the surface material needs to be identified but not necessarily quantified, then other techniques would be sufficient. The ability to quantify the surface composition of a sample accurately has a strong influence on the choice of analytical technique. The dynamic range, i.e., the variation in sensitivity to different elements or chemical species, must also be taken into account. For example, secondary ion mass spectrometry has sensitivity factors that differ over a million-fold range for different elements. This contrasts with Auger electron spectroscopy and X-ray photoelectron spectroscopy where the range of sensitivities differs by  $\sim 20$ -fold for different elements.

Spatial resolution is also important in surface analysis and the ability to resolve differences in surface composition on the nanometer scale is important in fracture analysis and many other areas. In this respect, secondary ion mass spectrometry has rather poor resolution, with a sample area generally in excess of  $7500 \text{ nm}^2$ . In contrast, techniques such as Auger electron spectroscopy, in which the probe diameter can be finely tuned, allow sample areas of  $70 \text{ nm}^2$  or less to be analyzed.

### Introduction

X-ray photoelectron spectroscopy (XPS) is the most broadly applicable surface analysis technique today. It relies on measurements of the energy distribution of photon-excited electrons from atoms in the surface region of the solid. It can detect all elements except hydrogen with a sensitivity that varies by only a factor of  $\sim 30$  across the periodic table. The absolute sensitivity is  $\sim 0.01\text{--}0.3\text{ at.}\%$  depending on the element. The electron-binding energies are sensitive to the chemical state of the atom and this is used to determine the chemical state of the atoms. Because of this feature, the XPS technique is also known under the acronym ESCA (electron spectroscopy for chemical analysis). It is a nondestructive technique (although damage by the X-ray beam can be significant in some organic materials) and in general it is less destructive than the other electron or ion impact techniques (Auger electron spectroscopy (AES) and secondary ion mass spectroscopy (SIMS)). The technique is highly surface sensitive with a probing depth of  $\sim 1\text{--}10\text{ nm}$ . The surface area detected can be as large as  $1\text{ cm} \times 1\text{ cm}$  or as small as  $3\text{ }\mu\text{m} \times 3\text{ }\mu\text{m}$ , and imaging XPS has become a common feature of the current generation of XPS spectrometers. In recent years, lateral resolutions in the  $100\text{ nm}$  range have been achieved by using the new generations of synchrotron light sources with high brightness. With special design of the spectrometer, XPS may be used to analyze gaseous and liquid samples, but it is mostly used for solids.

The photoelectron spectra can be generated using a primary beam of ultraviolet radiation (known as ultraviolet photoelectron spectroscopy (UPS)), or X-rays to yield an XPS spectrum. It can also be generated by synchrotron radiation (SR), in which case the electron spectrometer must be attached to the beam line at a synchrotron facility. UPS is essentially a molecular spectroscopy that provides high-resolution valence band spectra, while XPS is used predominantly to study core level transitions, and also to study valence band electrons.

### Principles of XPS

The physics of the XPS process is essentially straightforward. A primary beam of soft X-rays (usually Al  $K\alpha$  or Mg  $K\alpha$ ) interacts with the specimen. This leads to the excitation and subsequent ejection of low-energy electrons resulting from the photoionization of the atoms, molecules, or ions of the specimen. This is indicated in the schematic of **Figures 1A** and **1B**. The incoming photon of energy  $h\nu$  will, in this particular case, photoexcite a  $1s$  electron of binding energy  $E_B$  relative to the Fermi level; an additional term, the sample work function  $\Phi_{\text{sample}}$ , is needed to remove the electron from the solid. This energy is gained as the electron enters the spectrometer where it, in turn, has to overcome the work function  $\Phi$  of the spectrometer. Conservation of energy requires that

$$E_B = h\nu - E_K - \Phi \quad [1]$$

Thus, the determined electron-binding energy is independent of the work function of the sample. In the case of an insulator, the sample may become charged due to the emission of electrons during X-ray bombardment and the measured energy will be shifted. This is corrected for by setting a well-defined peak

**Figure 1** (A) Schematic of the XPS excitation process. (B) Schematic representation of the electron energy levels of an F atom and the photoionization of a F  $1s$  electron. (C) Auger emission relaxation process for the F  $1s$  empty-state produced in (B).

within the spectrum to its known binding energy value, e.g., carbon 1s to 285.0 eV.

The X-ray photoelectron spectrum is recorded either as a function of electron-binding energy  $E_B$  or directly as the kinetic energy  $E_K$  of the measured photoexcited electrons. The two are equivalent and are linked by eqn [1]. **Figure 2** shows the XPS spectrum of polytetrafluoroethene (PTFE). The use of PTFE as an example also illustrates another strength of XPS – its ability to analyze insulating materials. In addition to the ejection of the photoelectron, the photoionized atoms may relax by the emission of an Auger electron (see **Figure 1C**). In the Auger process, the empty core hole left behind after the photoexcitation (**Figure 1B**) is filled with an electron from one of the outer orbitals and the energy released is given up to a third electron that is emitted. This Auger electron is characterized by the levels involved and for fluorine, it is seen as a range of peaks (F KLL) corresponding to the possible combinations of the different  $L_1$ ,  $L_{2,3}$  energy levels involved (see **Figure 2**). The peak has a lower kinetic energy than the corresponding photoelectron and consequently it occurs at an apparent higher ‘binding energy’. For Auger electrons the ‘binding energy’ has no real physical significance and is a mere mathematical consequence of representing the observed electron energies by eqn [1]. Electron-excited AES is an important separate analytical technique, but much useful information can also be obtained from the X-ray-excited Auger spectrum. The Auger process involves typically one or more weakly bound valence electrons. Since the energy distribution of valence electrons may be strongly affected by the chemical bonds, the Auger peaks often contain considerable

information on the chemical state of the atoms. Details of the structure of the F KLL peak structures are thus markedly different for solids of different covalent character (e.g., NaF, NaBF<sub>4</sub>) and this is used as a fingerprint technique to distinguish between different chemical forms.

The electrons in the valence band, situated in the low-binding-energy region (0–35 eV), have peaks much less intense than the 1s (core level) peaks of carbon and fluorine, as a result of the very low photoelectric cross-section compared with the core levels. These features can be seen in **Figure 2**. The electron states in the valence band is studied extensively in UPS where use of low-energy photons make it possible to study transitions from occupied to unoccupied energy levels with high-energy resolution. At higher photon energies (typical of XPS), the excited electron is in a free electron state since it has an energy well above the Fermi level where the density of final states is featureless. The measured energy distribution in valence band XPS reflects therefore directly the density of occupied states. As a result, chemical bonding information may often be extracted from these spectra. **Figure 3** shows an example of spectra from carbon in three different forms (graphite, diamond, and ethylene) and it is clear that the valence spectral regions are distinctly different. This phenomenon is also used extensively to study variations in the electronic structure of alloys and semiconductor–metal interfaces.

## Qualitative Interpretation

The observed peaks in the XPS energy spectra of emitted electrons are essentially uniquely related to

**Figure 2** XPS spectrum of the polymer PTFE, showing the core level (carbon 1s and fluorine 1s, fluorine 2s at 31 eV and valence electron emission, X-ray induced Auger peaks (F KLL), and X-ray satellites ( $K_{\alpha 3,4}$  and  $K_{\beta}$ )). Note the step-like increase in intensity on the left-hand side of each major peak which is due to inelastically scattered electrons (see **Figure 7**).

**Figure 3** XPS valence band spectra of graphite, diamond, and polyethylene.

the binding energies of specific elements. Then by assigning the major peaks in a spectrum one readily determines which elements are present. Since the electron mean free path for the excited photoelectrons is only 0.5–3 nm the observed elements are situated in the outermost 5–20 atomic layers of the analyzed sample.

The assignment of the peaks, which, as described above, may be XPS transitions or their associated Auger peaks, is accomplished with the aid of a handbook or computer database of peak positions. All elements of the periodic table, with the exception of hydrogen, can be detected and XPS is able to analyze light elements with ease, a feature that makes it particularly attractive for the analysis of organic polymers. Minor X-ray satellites will be present if an achromatic X-ray source has been employed and arise from photoelectron transitions excited by the minor components ( $K_{\alpha 3,4}$  and  $K_{\beta}$ ) of such X-radiation. In **Figure 2**, the major photoelectron peaks (fluorine 1s and carbon 1s) are a result of Al  $K_{\alpha 1,2}$  induced photoemission. Features labeled  $K_{\alpha 3,4}$  and  $K_{\beta}$  arise from fluorine 1s electrons ejected by the Al  $K_{\alpha 3,4}$  and Al  $K_{\beta}$  components of the radiation, respectively. Instruments are often equipped with a monochromator that remove the  $K_{\alpha 3,4}$  and  $K_{\beta}$  satellite lines from the beam of X-rays.

## Chemical Analysis

The chemical information implicit in the X-ray-induced photoelectron spectrum is a very important feature of the XPS technique and is, as mentioned above, the source of the alternative acronym ESCA. For almost all elements the binding energy of the photoelectron peak shows small perturbations that reflect the chemical environment of the element under consideration.

As mentioned above, both the valence region of the spectrum and the Auger peaks give information on the chemical bonding because the bonds will usually change the density of states in the valence band. However, the most important source of chemical state information in XPS comes actually directly from the energy position of the photoelectron core level peaks. Although the core levels are not directly involved in the chemical bonding process, their binding energy depends on the chemical environment. In a simplified picture, this effect, which is called the ‘chemical shift’, originates from the change in electrostatic potential inside the orbitals of the valence electrons (i.e., at the location of the core electrons). Thus, as the effective valence electron charge around a given atom changes by the amount  $\Delta q$ , the potential of all core electrons of this atom changes by  $\Delta q/(4\pi\epsilon_0 r)$ , where  $r$  is the radius of the valence electron orbital, and the core level binding energies change correspondingly. Large variations in chemical shifts are thus expected for different oxidation states but can also arise from difference in lattice site and molecular environment. In a more accurate model, the electron orbitals cannot be assumed to remain frozen during photoemission and the electron-density around the atom relaxes in response to the creation of the positively charged core hole. This reduces the kinetic energy of the outgoing photoelectron and thereby increases the derived electron-binding energy. These effects are known as shake up and may be seen as distinct features in the spectrum (see below).

An example of the chemical shift phenomenon is illustrated in **Figure 4**, which shows the Si 2p peak from a thin SiO<sub>2</sub> film on a Si substrate. This ability to distinguish between Si and SiO<sub>2</sub> is widely used by the semiconductor industry to monitor the morphology of nanometer thin SiO<sub>2</sub> structures. **Figure 5** shows the carbon 1s spectrum of a complex fluorocarbon surfactant. The experimental spectrum is indicated by the individual points and the computer convolution of the various components is represented by the solid line. Components resulting from carbon in the following chemical states are identified as C–H and C–C (lowest binding energy), C–O and C–N, C=O,

**Figure 4** Si 2p spectrum from a thin  $\text{SiO}_2$  film grown on a Si substrate. The  $\text{SiO}_2$  film is  $\sim 3.2$  nm thick.

**Figure 5** C 1s spectrum of a complex fluorocarbon surfactant. The assignment of the individual components is as follows: (left to right) C–H and C–C (285.0 eV), C–N and C–O (286.4 eV), C=O (287.8 eV), C–F (290.2 eV), C–F<sub>2</sub> (291.8 eV), C–F<sub>3</sub> (294.2 eV).

C–F, C–F<sub>2</sub>, and C–F<sub>3</sub> (highest binding energy). The low-intensity feature at 282 eV is the CF<sub>2</sub> component excited by the Al K $\alpha$  X-ray satellite. The binding energy of the carbon 1s electrons increases as they become associated with the more electronegative atoms; this shift also increases with the number of fluorine atoms attached to each carbon. Such a positive binding energy shift is not always observed; in the case of sulfur, a positive shift (relative to elemental sulfur) is seen for the sulfate ion, but a negative shift is observed in the case of a sulfide. The same phenomenon is observed in the carbon 1s spectrum of carbide compounds.

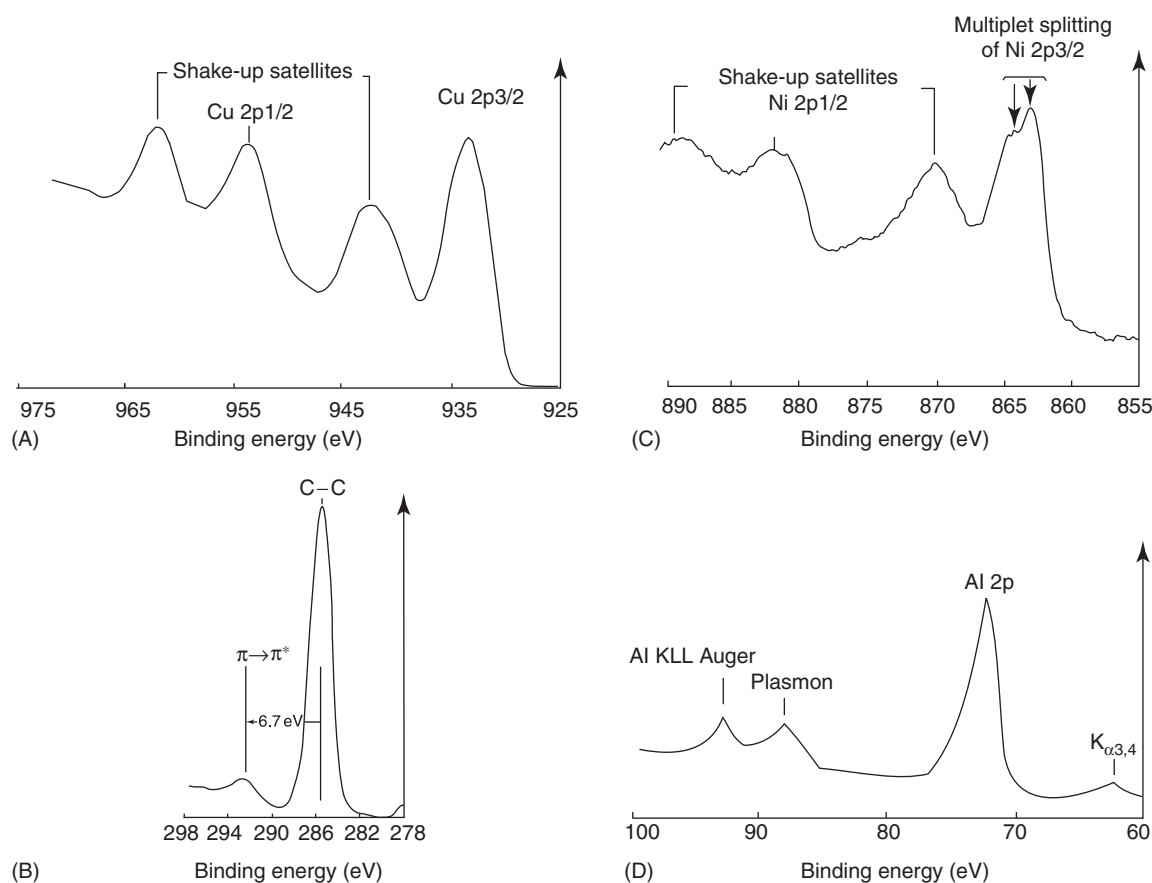

Such core level shifts are well documented in handbooks and databases and are widely used to get chemical state information. But in some cases, the change in potential is insignificant although the valence electrons are changed considerably due to

different chemical bonds. In such cases, it is of value to examine those transitions that are directly affected by the valence electron distribution (i.e., the valence band region and the Auger peaks). As an example, **Figure 3** illustrates the valence band spectra of three forms of carbon: polyethylene, graphite, and diamond. The carbon 1s core level spectra of these three materials are very similar, but the valence band spectra (carbon 2s and 2p electrons) are very characteristic and provide a ready means of differentiation between the three materials. When recorded at better energy resolution it is even possible to differentiate between individual polyolefines and their conformations. Although this region of the spectrum is not amenable to elemental quantification, it is possible to use such spectra in conjunction with molecular orbital calculations, or merely as a ‘fingerprint’ of a specific material. Another example is copper oxides. While the Cu 2p peak in CuO is shifted by  $\sim 1.5$  eV relative to Cu (metal), the Cu 2p peak in Cu<sub>2</sub>O is not shifted. Here, the three forms of Cu can, however, be easily distinguished by shifts in their Auger peaks. Thus, the L<sub>3</sub>VV peak is shifted by  $\sim 0.6$  eV for Cu<sub>2</sub>O and by  $\sim 1.9$  eV for CuO relative to Cu (metal).

## Energy Loss Features in the XPS Spectrum

The outgoing photoelectron may interact with electrons in the solid which gives rise to additional energy loss processes that will lower the measured kinetic energy of the electron and yield additional features in the XPS spectrum at a binding energy slightly greater than the core level peak.

The processes are traditionally divided into two types. The first type is known as ‘final-state effects’ or ‘intrinsic excitations’ that take place at the time immediately after the photoexcitation process before the photoelectron has moved away from the atom. Thus, the interaction with the suddenly created core hole gives rise to excitations of valence electrons to empty states in the valence band, known as ‘shake-up’ processes. This reduces the kinetic energy of the emitted core electron slightly and consequently it appears at a slightly higher binding energy within the photoelectron spectrum as a characteristic satellite structure. Shake-up satellites occur in several classes of spectra, the most notable being the 2p spectra of the d band metals as shown in the copper 2p spectrum of CuO in **Figure 6A**, and the bonding to antibonding transitions of the  $\pi$  molecular orbitals in aromatic organics, **Figure 6B**. A related process is that of ‘shake-off’, in which the valence electron is ejected to higher energy levels. Because the density of

**Figure 6** Extrinsic and intrinsic loss features in XPS. (A) CuO: Cu 2p shake-up satellites, (B) C 1s and  $\pi \rightarrow \pi^*$  shake-up satellite, (C) NiO: Ni 2p shake-up and multiplet splitting, and (D) Al plasmon loss feature from pure aluminum.

these final states is broad and featureless, such losses generally occur as a very broad feature within the large background of inelastically scattered electrons.

Multiplet splitting of a photoelectron peak may occur in a compound that has unpaired electrons in the valence band. The effect arises because an unpaired core electron that remains after the photoemission will couple to unpaired spin electrons in the valence band and this leads to more than one final state peak which is seen as a peak splitting. Since the distribution of unpaired electron spins in the valence band changes with the chemical bonding so does the size of the multiplet splitting. Multiplet splitting effects are observed in cobalt and nickel (2p levels), manganese and chromium (3s levels), and the rare earths (4s levels). The spectrum of nickel(II) oxide in **Figure 6C** illustrates the diagnostic utility of such features; the multiplet splitting exhibited by this compound distinguishing it quite conclusively from nickel(II) hydroxide from which it is absent.

The second type of loss features, known as 'extrinsic' effects, occur during transport of the photoelectron from the emitting atom to the surface of the

**Figure 7** Schematic of the loss of peak intensity with increasing excitation depth and the corresponding rise in intensity of inelastically scattered electrons at lower kinetic energies  $E_K$ .

solid where the electron will excite valence electrons of the solid by plasmon and interband excitations. The distribution of energy loss depends characteristically on the distance traveled and thereby on the depth distribution of photon-emitting atoms. The situation is illustrated in **Figure 7**. Analysis of

the measured XPS peak shape in a 50–100 eV energy range is therefore used to determine the depth distribution of atoms (see below). In general, the extrinsic energy losses is rather featureless but for some solids, with distinct structure in the valence band density of states or with very narrow plasmon excitations, these inelastically scattered electrons may be seen in the spectrum. This is seen for SiO<sub>2</sub> in Figure 4 and for aluminum in Figure 6D.

## Depth of Analysis in XPS

The photoelectrons in XPS with typical energies in the 100–1500 eV range can only travel a short distance in the solid before they lose energy. This is the reason for the high surface sensitivity of XPS. If  $I_0$  is the flux of electrons originating at depth  $z$ , the flux detected at the peak energy, i.e., without energy loss is

$$I_d = I_0 \cdot e^{-z/(\lambda \cos \theta)} \quad [2]$$

where  $\theta$  is the angle of electron emission and  $z/\cos \theta$  the distance traveled through the solid. The quantity  $\lambda$  is the electron attenuation length that depends on several factors but the most important is the electron kinetic energy. As a general guide, this parameter varies as  $E_K^{0.75}$ . Values of  $\lambda$  are usually in the range of 0.5–2 nm for the electron energies of interest in XPS. From eqn [2] it follows that 65% of the photoelectron peak signal emanates from a depth of  $1\lambda$  (at normal electron emission), 85% from  $2\lambda$ , and 95% from  $3\lambda$ . The analysis depth in XPS is often taken as three times the electron attenuation length, although it must be appreciated that the analysis obtained within such a depth is heavily biased toward the outer region of the specimen for the reasons outlined above. This gives a characteristic analysis depth of 1.5–6 nm. Additional surface sensitivity in XPS may be obtained by tilting the sample within the spectrometer and thus changing  $\cos \theta$ . The reduction of the electron take-off angle in this manner, to reduce analysis depth, is known as angular-resolved XPS, which is also used to get information on the in-depth distribution of atoms.

As described above,  $\lambda$  is a function of electron kinetic energy and in the XPS experiment this can be varied for the electron orbital of interest by changing the photon source energy. In the laboratory this can be achieved by using an alternative conventional X-ray source (e.g., Al K $\alpha$  or Mg K $\alpha$ ,) or by increasing the analysis depth by using a high-energy source (e.g., Zr L $\alpha$ , Ag L $\alpha$ , or Ti K $\alpha$ ). SR can be extremely useful in this respect as it becomes possible to match the kinetic energy, and hence the analysis depth, for

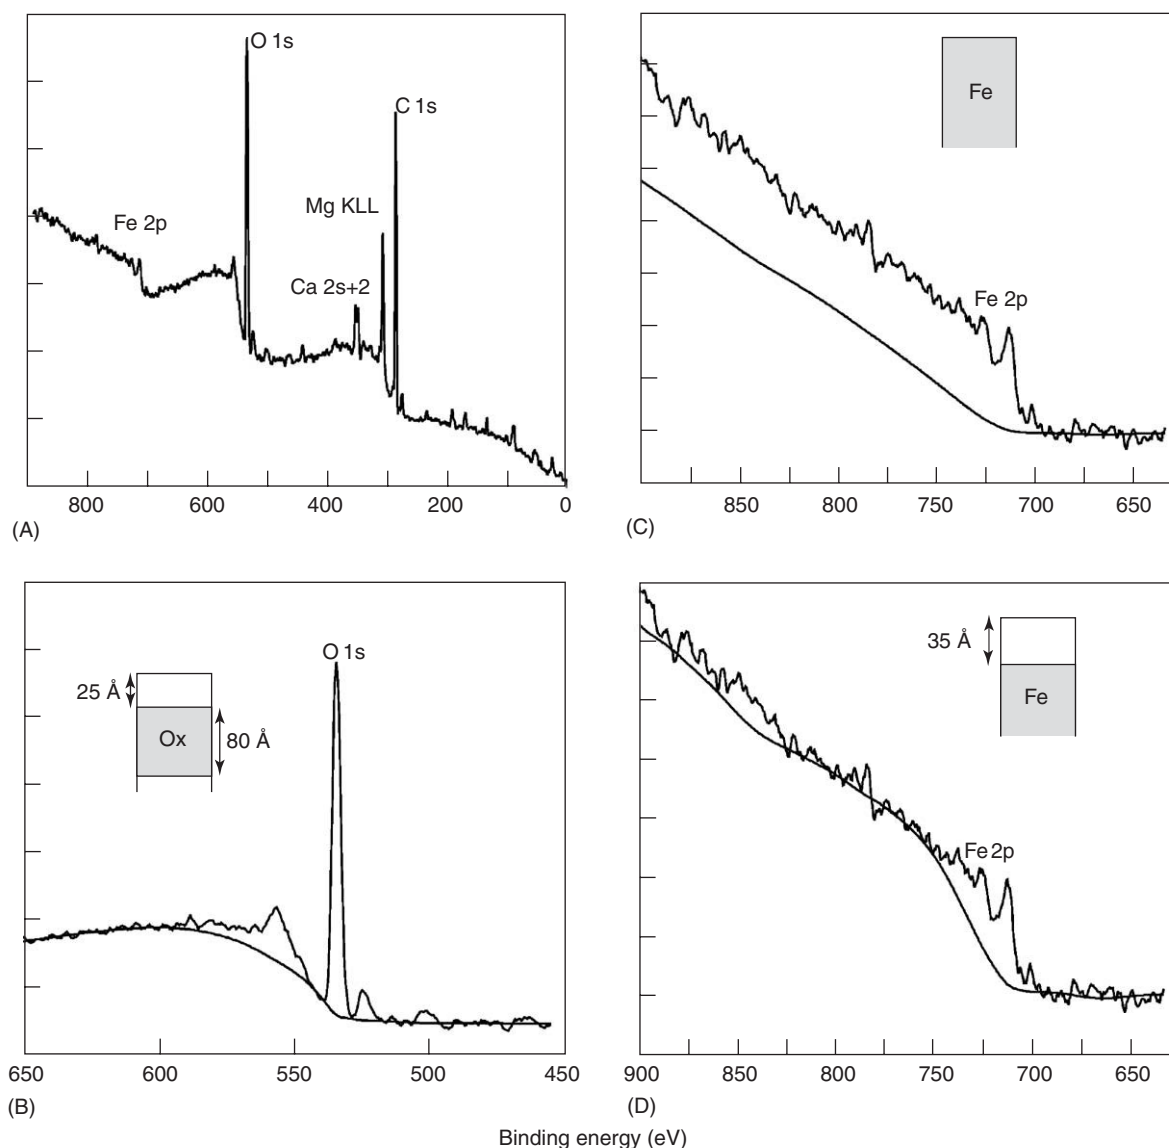

each electron orbital to be studied. This has been used to great effect in the study of semiconductor interfaces.

## Quantitative Interpretation of XPS

Quantification is simple if the atoms are homogeneously distributed with depth since the intensity of each XPS peak is then directly related to the abundance of that particular element at the specimen surface. The peak intensity will usually be reported as a peak area and this will be normalized using atomic sensitivity factors (the intensity of the photoelectron transition of interest,  $I$ , is related to the concentration of that element within the XPS analysis volume, and the sensitivity factor,  $S$ , in the following way:  $I = \text{concentration} \times S$ ). Such atomic sensitivity factors are a function of the basic physical parameters, such as the relative photoelectron cross-sections of the different elements, electron attenuation lengths, and instrumental parameters, such as analyzer transmission functions, of the XPS experiment. The ratio of normalized peak area to the sum of normalized peak areas for the major peaks of all elements detected in the spectrum provides an analysis as an atomic fraction (or when multiplied by 100, atomic %).

If the depth distribution is not homogeneous over the analysis depth, this quantification scheme is not valid because of the strong signal attenuation with depth (eqn [2]). It is simple to correct for this, if the in-depth distribution is known. But since this is rarely the case, it is customary to still use the above simple quantification scheme that assumes a homogeneous depth distribution; however, the resulting quantification is then quite inaccurate. The accuracy is improved considerably by analysis of the XPS peak shape in a 50–100 eV energy region around the peak. This is because photoelectrons that are ejected from atoms close to the surface have a low probability for energy loss and most of these will end up at the original excitation energy, i.e., at the peak energy. Photoelectrons that are excited from atoms at larger depths will have a much lower chance of escaping without energy loss and most of these will end up in the broad background at lower kinetic energies as shown schematically in Figure 7. The shape of the peak region including the continuous background of inelastically scattered electrons is therefore characteristic of the in-depth distribution of emitting atoms and the in-depth distribution of atoms can be determined by analysis of this energy distribution. A practical example of this is in Figure 8A, which shows the XPS spectrum of an iron sample that has been

**Figure 8** (A) XPS of an iron sample that has been exposed to a corrosive marine environment. The presence of Fe, O, C, Mg, and Ca are seen. The C and Ca peaks have high intensity and rather low steps in background intensity and these atoms must therefore be near the surface (according to **Figure 7**). The Fe 2p peak has a low intensity and a steeply rising background of inelastically scattered electrons which readily shows that the iron concentration increases with depth, (B) Quantitative analysis of the O 1s peak shape shows that the oxide forms a 80 Å thin film covered by an overlayer of ~25 Å (of predominantly C and Ca). The analysis of the Fe 2p peak shape in (C) and (D) shows that the Fe concentration is not constant with depth but the Fe substrate is covered with a ~35 Å iron-free overlayer.

exposed to a corrosive marine environment. The presence of Fe, O, C, Mg, and Ca are seen. The C and Ca peaks have high intensity and rather low backgrounds and these atoms must therefore be near the surface. The Fe 2p peak has a low intensity and a steeply rising background of inelastically scattered electrons, which readily shows that the iron concentration increases with depth. In comparison, the O 1s peak has high-peak intensity and a relatively lower background that indicates that it is closer to the surface. Quantification of the peak shapes is done by

application of an integrated software package that simulates the inelastic background for assumed depth distributions which are varied until good account is found. The analysis assuming different distributions of Fe (**Figures 8C** and **8D**) shows that the sample consists of Fe which is covered by ~35 Å overlayer while a similar analysis of O 1s (**Figure 8B**) reveals the depth distribution of oxygen. The Mg KLL peak is mixed with the C and Ca peaks and therefore requires a more elaborate analysis of the background.

**Figure 9** XPS of a diblock copolymer that consists of poly(styrene)–poly(dimethylsiloxane) (PS–PDMS). PDMS contains oxygen atoms which are not in PS and the shape of the O 1s peak can be used to distinguish the in-depth distribution of the two polymer blocks.

Figure 9 shows the XPS spectrum of a diblock copolymer that consists of poly(styrene)–poly(dimethylsiloxane) (PS–PDMS). PDMS contains oxygen atoms that are not in PS and the O 1s peak can be used to distinguish the distribution of the two polymer blocks. The O 1s peak intensity increases gradually and the inelastic background decreases as the sample is annealed, which shows that PDMS segregates to the surface. The quantitative nanostructure of the polymers can be determined as above by computer simulation of the peak shape. Alternative possibilities to determine if a sample is homogeneous and to distinguish the composition of the outermost surface from the bulk is by varying  $E_K$  or by varying the emission angle as was discussed in the previous section.

### Spatial Resolution in XPS

There has been a strong drive to see the unique advantages of XPS applied to smaller and smaller surface areas and imaging XPS has now become a common feature of the current generation of XPS spectrometers. Today, areas of  $\sim 100\mu\text{m} \times 100\mu\text{m}$  are the typical lower limit with conventional spectrometers and X-ray sources. Using a scanning XPS microprobe to produce a focused X-ray beam on the sample, lateral resolutions of  $\sim 3\mu\text{m}$  is obtained in

the best commercial instruments. With the new generations of synchrotrons, it has been possible to increase the lateral resolution tremendously due to their high brightness. Today lateral resolutions better than  $\sim 100\text{nm}$  is routinely achieved and in the near future it is expected that  $\sim 2\text{--}5\text{nm}$  resolution will be reached. This development will open up a new exciting area of applications. However, the time required to get sufficient signal-to-noise ratio at high lateral resolution increases considerably.

### Instrumentation for XPS

The illustration of Figure 10 is a schematic diagram of a commercial electron spectrometer. The essential features are an X-ray source, the specimen, an electron transfer lens, an electron energy analyzer, and an electron detector (channel electron multiplier or channel plate), all contained within an ultrahigh vacuum (UHV) chamber. A lens system is used in front of the entrance slit of the hemispherical analyzer to provide a comfortable free working range of typically 30–50 mm above the sample. The lens system is typically designed with a multielement zoom lens type that can easily be set to operate at different magnifications. This is used for an easy variation of the analyzed area of the sample and for imaging.

**Figure 10** Schematic of a typical XPS spectrometer.

The X-ray source is generally of a twin anode design providing a broad beam source of Al  $K\alpha$  ( $h\nu = 1486.6$  eV) or Mg  $K\alpha$  ( $h\nu = 1253.6$  eV) X-radiation. Other sources can be used to probe deeper core levels. Possible high-energy photon sources for XPS include Si  $K\alpha$  (1740 eV), Zr  $L\alpha$  (2042 eV), and Ag  $L\alpha$  (2984 eV). One factor that limits the spectral resolution attainable in XPS is the natural linewidth of the X-ray source. This can be reduced substantially, and the extraneous radiation such as X-ray satellites and Bremsstrahlung removed, by the use of a crystal monochromator by which the spectral resolution is improved substantially as the X-ray linewidth is reduced from 0.85 eV to  $\sim 0.35$  eV, but the intensity is also reduced.

The only restriction on the solid sample in XPS is that it is vacuum compatible, although even this may

be relaxed as a cryo-stage, or differential pumping in the region of the specimen, will often be available. The limit on sample size depends on the mode of sample handling but a  $1\text{ cm}^2$  sample is the optimum size for most spectrometers. During analysis the sample will be located on a holder within a high-precision manipulator. An inert gas ion gun is used to remove material by ion sputtering and when used sequentially with XPS it is a convenient way to make a compositional depth profile to a depth of  $\sim 1\text{ }\mu\text{m}$ .

The XPS spectrum is typically recorded with a hemispherical sector analyzer. The general configuration of the analyzer is seen in **Figure 10**. By applying appropriate potentials to the hemispheres and prere-tardation grids it is possible to select the energy of the electrons that will reach the electron multiplier. The spectrum is then acquired by scanning these

potentials. The electron detection stage of the analyzer is a channel plate or more usually a channel electron multiplier, which today are used in arrays of five, seven, or more to enhance the energy resolution and signal strength.

This hardware is all enclosed in a UHV chamber with pressure below  $\sim 10^{-9}$  mbar, constructed of or shielded by, a low magnetic permeability material such as mu-metal. This is necessary to avoid the field from the Earth and nearby magnetic objects to affect the electron trajectory. The UHV requirement is, in part, a result of the very surface sensitivity of XPS itself. At a vacuum level of  $10^{-6}$  mbar a monolayer of gas is adsorbed on a solid surface in a few seconds if the surface atoms are reactive to the gas. At a vacuum of  $10^{-9}$  mbar (UHV) the time to form an adsorbed monolayer is several hours.

The final component of an XPS spectrometer, and one that has been alluded to several times already, is the data system for control of the spectrometer, X-ray sources, other hardware items such as auto-carousel, ion gun, and analysis position in small-area XPS and imaging XPS. This will record the spectrum or image and retain it for further data processing such as quantification or curve fitting. Such a computer system is an integral part of the spectrometer and is provided by the manufacturer when the instrument is purchased.

## Applications

XPS is probably the most widely used of the 'popular' surface analysis methods that are generally available (the others being AES and SIMS). This is due to its unique advantages – that it readily gives chemical state information, is easily quantifiable, and applicable to insulators. The principal disadvantages are that it has lower spatial resolution although this has improved tremendously over the past decade and that it has a detection limit of  $\sim 0.1$  at.%. This latter value is rather better than AES but is well removed from that of SIMS which can be in the  $\text{ng g}^{-1}$  range in favorable cases.

In this section, a few typical applications of XPS will be presented to illustrate the type of information that is readily attainable. Although the examples quoted are invariably parts of larger research programs, they illustrate the type of information that can be obtained quite readily within a very short space of time, perhaps by buying a single day of instrument time from a consultancy organization.

### Corrosion

In the examination of corrosion processes, there are usually two considerations of interest: the chemical

nature of the corrosion product (which may be a passive *film*) and the electrochemical history of the specimen. The subsequent breakdown of the passive film and other localized corrosion phenomena are generally studied by scanning Auger microscopy (SAM) but with the improvements that have taken place in imaging XPS and the inherent difficulties with SAM (possible beam damage and image instability resulting from electrostatic charging of thick corrosion products), XPS is now important in these investigations as well.

Figure 8 shows, as already described above, how nanothin oxide films can be easily quantified. Figure 11 shows the aluminum 2p spectrum of aluminum foil covered with a thin, oxide layer formed by exposure to air. The contributions from the metallic substrate, at a binding energy of 73 eV and the oxide over-layer aluminum 2p peak shifted to 76 eV, are easily distinguished in the experimental spectrum. By computer peak fitting of the spectrum it is possible to determine (as peak areas) the relative contribution from the two chemical states of aluminum. A chemical shift of this type is exhibited by almost all metals and provides a convenient way of separating the oxide component from its parent metal. In metals of variable valency it may be necessary to resort to an additional method of confirming the oxidation state, e.g., in copper compounds the X-ray-induced Auger peaks together with the CuO shake-up satellite of Figure 6A, when all taken together, provide unambiguous identification of Cu(metal),  $\text{Cu}_2\text{O}$ , and CuO.

If the overlayer is flat and covers the surface as a uniform layer, the oxide thickness,  $d$  is

$$d = \lambda \sin \theta \ln(I_{\text{oxide}}/I_{\text{metal}} + 1)$$

This does not apply if the surface is rough or if the layer is not uniform and then analysis of the peak shape may be used to determine the nanostructure of the film as discussed above (Figure 8). The electrochemical history of a specimen may be readily

**Figure 11** Al 2p spectrum from an oxidized aluminum foil. The oxide is  $\sim 3.8$  nm thick.

estimated by a surface-sensitive method such as XPS. This arises from the fact that if a metal electrode is polarized cathodically in an aqueous solution it will preferentially retain cations on removal, which are identified in the electron spectrum. The reverse is true of anodically polarized electrodes.

### Polymer Analysis

XPS provides a powerful method for the surface analysis of polymers and is employed routinely for this purpose in many laboratories around the world. All the constituent elements of organic polymers, with the exception of hydrogen, are detectable and have chemical shifts that indicate their chemical environment. An example of the segregation of a diblock copolymer during annealing is shown in **Figure 9** where the quantitative nanostructure of the PDMS segregation to the surface is determined by analysis of the peak shape. Combination of XPS with time-of-flight SIMS, which provides molecular specificity, improves the information attainable. The main advantage of XPS for many polymer applications is, however, obtained from the peak energy and peak fitting of the C 1s spectrum, as this provides chemical information that is superior to that provided by other characteristic spectra of polymer constituents. The type of information attainable in this manner is illustrated in the carbon 1s spectra of **Figure 5**. As indicated in an earlier section, the XPS valence band spectra of polymers can be extremely informative for the characterization of such materials.

### Adhesion Science

In adhesion science, the concern is often to identify the exact locus of failure between two dissimilar materials. XPS can easily identify and quantify very thin organic overlayers on metallic substrates and it is widely used in adhesion studies. In addition, the manner in which aggressive species (such as water or ions) that bring about adhesion failures aggregate at or near the interface can be monitored.

### Microelectronics and Other Areas of Application

In addition to the brief examples quoted above, XPS is widely employed in many other areas including, among others, microelectronics and thin film technology, catalysis, tribology, and oxidation.

### Introduction

Particle-induced X-ray emission (PIXE) is a technique for elemental analysis using a beam of high-energy particles as probe and characteristic X-rays of the elements as analytical signal. The value of the technique was first demonstrated at the Lund Institute of Technology (Sweden) in 1970. Since then, PIXE has grown to maturity, a growth that can be

followed by surveying the proceedings of the triannually organized PIXE conferences as well as those of the regular International Conferences of Nuclear Microbeam Technology and Applications.

Although frequently used as a bulk technique, PIXE is surface sensitive owing to the limited range of the impinging ions in matter. The availability of dedicated accelerators producing ions in the MeV region and, even more important, the development of microprobes with ion beams focused down to below 1  $\mu\text{m}$ , give PIXE a secure place among the various microanalytical techniques. It is important to note that if MeV ions are incident on a specimen, multi-signal detection will lead to a more complete characterization of that specimen. PIXE is therefore very often used in combination with methods such as Rutherford backscattering and nuclear reaction analysis.

This article describes the potential of PIXE, its properties, and figures of merit, and a number of illustrative applications.

## Theory

PIXE relies on the Coulomb interaction between the incoming ions and inner-shell electrons in order to create vacancies in the K-shell (or for high-atomic number elements the L-shell), after which characteristic X-rays are emitted. The cross-section of the process of inner-shell ionization was initially described in the plane-wave Born approximation (PWBA) or a binary encounter model, but recently almost exclusively the so-called ECPSSR treatment is in use. This theory is a modification of the PWBA description and includes the deflection and velocity change of the projectile owing to the nuclear Coulomb field ( $C$ ), the perturbation of the atomic stationary states (PSS) by the projectile, relativistic effects ( $R$ ), and energy loss ( $E$ ) during the collision. These corrections are treated as a series of modifications to the projectile energy and the binding energy (using effective energies) of the inner-shell electron involved.

The projectile energy of interest for PIXE is commonly considered as being between 1 and 4 MeV for protons. Although this is not the energy where the cross-section is at its maximum (which is the case if the velocity of the projectile matches the velocity of the orbiting electron), these energies provide the highest peak-to-background ratio. This is because of the low values of cross-sections for nuclear events, which occur simultaneously with inner-shell ionization, and because of limitations on the maximum energy that can be transferred to electrons. This

energy transfer is important, as the major contribution to the background in PIXE spectra is the continuum bremsstrahlung X-radiation emitted during the deceleration of secondary electrons. To shift this continuum to lower energy values it is necessary to lower the incident particle energy that leads to reduced inner-shell ionization cross-sections. There is therefore a compromise between a reasonable cross-section for inner-shell ionization and an acceptable background at the position in the spectrum where the analytical signal is expected. The bremsstrahlung background is also dependent on the composition of the matrix; higher-atomic number elements with a higher electron density will give rise to both an increased background level and a shift toward higher energies owing to the collisions of protons with bound electrons. In **Figure 1**, typical backgrounds are given for a number of elements irradiated with 2.5 MeV protons. The low-energy cutoff is caused by the filtering of low-energy X-rays by the detector window. The proton energy for which the best detection limits (or the best signal-to-noise ratios) can be expected has been calculated by several authors and lies between 1 and 3 MeV for protons, the most frequently used projectile. ECPSSR cross-sections for particles of this energy are extensively tabulated for PIXE users.

The yield of characteristic X-rays for a given element  $Z$  is proportional to the amount of the element  $Z$  and can be written as

$$Y(Z) = \frac{N_p M(Z)}{S} \frac{\sigma_Z(E_0) \omega_Z b_Z \epsilon_Z N_0}{A_Z} \quad [1]$$

where  $M(Z)$  and  $A_Z$  are the mass present and the relative atomic mass of the element,  $\sigma_Z(E_0)$  is the

**Figure 1** Typical background spectra for a number of common matrix elements for 1  $\mu\text{C}$  accumulated charge of protons using energy-dispersive detection with a Si(Li) detector.

ionization cross-section (in  $\text{cm}^2$ ) for proton energy  $E_0$ ,  $\omega_Z$  is the K- or L-fluorescence yield,  $b_Z$  is the fraction of X-rays that appear in the  $K_\alpha$  or  $L_\alpha$  line,  $\varepsilon_Z$  is the absolute detection efficiency including the absorption in windows of the scattering chamber and the detector,  $N_p$  is the number of protons incident on the sample, and  $N_0$  is Avogadro's number.  $S$  is the area of the beam spot (in  $\text{cm}^2$ ). Equation [1] describes the situation of a homogeneous beam that envelops the sample. If the beam only covers a part of the specimen, it is customary to express the analyte in  $\text{g cm}^{-2}$  (area density).  $M(Z)$  in eqn [1] is then replaced by  $M_a(Z) \times S$ , where  $M_a$  is the area density. This has the advantage that  $S$  cancels out. The same formula is applicable whether the beam envelops the specimen or not.

Equation [1] only holds for thin specimens. Thin means that (1) the energy loss of the proton beam is so small that one can consider  $\sigma_Z(E)$ , which is energy dependent, as being constant; and (2) one can neglect absorption of X-rays in the specimen on their way to the detection system. As an example, for biological sections, often a few micrometers thick, proton energy loss is sufficiently small so that eqn [1] applies. The self-absorption depends on the analyte; for light analyte elements correction procedures are needed. For thin specimens it should be possible to perform absolute analysis with accuracy within 10% provided that the overall efficiency of the detector,  $\varepsilon_Z$ , is adequately calibrated and the accumulated charge,  $N_p$ , is monitored properly.

If the specimens are thicker, correction algorithms are necessary. In eqn [1],  $\sigma_Z(E_0)$  has to be replaced by the integral over this cross-section from the incoming ( $E_0$ ) to the outgoing proton energy (or, if specimens are thicker than the range of the projectiles, to 0). Moreover, for the outgoing X-rays, the attenuation as a function of depth of their origin has to be calculated. These calculations are invariably done numerically by dividing the specimen into a number of layers. For each layer, eqn [1] is applied with the cross-section for the proton energy in that layer and with an extra attenuation term to take into account self-absorption. Several computer programs are available to do these calculations. These calculations, however, can only give accurate results if one has a detailed knowledge of the matrix composition, because this composition determines both the energy loss of the beam and the attenuation of X-rays in the specimen. If this composition is not known, RBS analysis performed simultaneously can be very helpful. The accuracy of thick target analysis is less than for thin specimens because of uncertainties in the database needed for these correction procedures. Frequently, standards with comparable matrix

composition as the unknowns are used to improve accuracy.

The minimum detection limit (MDL) also depends on target thickness. If the MDL is defined in the usual way as being the concentration for which the corresponding X-ray line intensity (yield) exceeds three standard deviations of the background in that spectral region, it can be shown that for a thin specimen the MDL is proportional to

$$\frac{\sigma_B^{1/2}}{\sigma_Z} \left( \frac{\text{FWHM}}{N_p \varepsilon_Z} \right)^{1/2} \quad [2]$$

in which  $\sigma_B$  is the production cross-section of background in the spectral region of the characteristic peak of element Z, FWHM is the full-width at half-maximum of this peak, and  $N_p$  is the number of protons incident on the target.

Other definitions of MDL are sometimes used. For ease of calculation some authors define the requirement that the counting rate of the peak is equal to the counting rate of the background, which results in a peak-to-background ratio of 1. In Figure 2, the results of calculations of MDL for a carbon matrix are given for both thin and thick targets. These results hold for energy-dispersive detection with a Si(Li) detector. Figure 2 illustrates well the main features of the MDL, showing a minimum around  $Z=30$ , a minimum that is shifted upwards by increasing the proton energy. It illustrates the advantages of using a thin specimen, especially for heavier analyte elements. Also shown is that in optimal conditions, MDL values are  $0.1 \mu\text{g per g}$ . It should be noted here that absolute MDL values can be very low indeed since the irradiated sample mass, especially with well-focused proton beams, can be as low as a few nanograms, leading to absolute values of MDL in the femtogram region. It is also worth noting that research with other ion beams, especially beams of  $\alpha$ -particles, has demonstrated that at  $\sim Z=20$  lower relative MDL values ( $10^{-2} \mu\text{g per g}$ ) can be obtained.

## Instrumentation

PIXE instruments are normally divided into two groups, those instruments suitable for macro-PIXE with a beam with cross-section of several  $\text{mm}^2$ , and those suitable for micro-PIXE with a beam spot of  $\sim 1 \mu\text{m}^2$  cross-section. The obvious requirement for both PIXE facilities is the availability of an ion accelerator capable of producing beams of a few megaelectronvolts. In the early days of PIXE, parasitic use of accelerators purchased for research in nuclear physics was common. The majority of these

**Figure 2** Detection limits as a function of  $Z$  for two proton energies and for thin and thick specimens. The minimum detection limit is defined here as the concentration giving a peak-to-background ratio of 1. The calculations are done for a carbon matrix. (Reprinted with permission from Vis RD (1985) *The Proton Microprobe: Applications in the Biomedical field*. Boca Raton, FC: CRC Press; © CRC Press.)

machines were of the Van de Graaff type; at a few places cyclotrons were employed for PIXE. The mainstream research in nuclear physics shifted toward higher-energy machines and nowadays at several institutes accelerators are fully dedicated for ion beam analysis. Recently, a few laboratories have acquired modern electrostatic accelerators, especially produced for analytical work. These machines feature a high stability and a good energy resolution of the beam and are more user-friendly. They are often of the tandetron type, with a solid-state diode stack to provide the high potential, or of the pelletron type, in which a chain of pellets rather than a belt carries the charge toward the terminal. Both single-ended and tandem machines are in use.

### Macro-PIXE

For macro-PIXE, the accelerator has to be equipped with a beam-guiding system to transport the beam to the sample chamber. This beam transport system encompasses one or more bending magnets, focusing quadrupole magnets, and beam steerers for minor corrections. The whole system should be evacuated to a pressure below 1 MPa. In **Figure 3A**, the various features of a PIXE chamber are illustrated. The PIXE chamber has (1) diaphragms to collimate the beam to the desired dimension; (2–4) a sample changer; (5) an X-ray detector; (6) absorbers to filter out low-energy X-rays in order to limit the total counting rate of the detector(s); and very often also (7), a  $\gamma$ -detector for the detection of  $\gamma$ -rays resulting from nuclear reactions on low- $Z$  elements and (8) an in-angle adjustable surface barrier detector (SBD) for RBS. The

chamber has a Faraday cup to monitor the beam. Electronics for data acquisition are standard; after amplification the signals are fed into a multichannel analyzer. **Figure 3B** shows a complete setup used for both macro- and micro-PIXE.

### Micro-PIXE

Since around 1980, nuclear microprobes, sometimes also referred to as ion microprobes (not to be confused with the low-energy ion microprobe for SIMS), have been developed. These are instruments in which the ion beam is focused to micrometer dimensions. All nuclear microprobes consist of an object slit for primary collimation, followed by one or two additional slit pairs to intercept scattered particles and to limit the divergence of the beam, and a lens system. The lens is normally a set (2–4) of high-precision magnetic quadrupoles. At the present stage of development beam spots can be produced of below  $0.5\ \mu\text{m}$  diameter with sufficient current (50–100 pA) to analyze at trace level. However, the quality of state-of-the-art microbeam optical channels can be characterized by the fact that spot sizes of  $35 \times 75\ \text{nm}$  have recently been measured in scanning transmission ion microscopy mode at a beam current as low as 10 000 protons per second. The specimen chamber for micro-PIXE is more complicated than that for macro-PIXE because in addition high-precision positioning of the specimen is needed and the sample has to be viewed by an optical microscope for tuning purposes and for proper definition of the scan area. Scanning can be performed either by moving the target or by sweeping the beam with deflection

(A)

(B)

coils. In both cases, fast electronics should correlate the detector events with the position along the scan in order to be able to construct trace element concentration maps. **Figure 4** is a schematic representation of a micro-PIXE chamber. Data storage is often done in list mode, which means that every detector event is labeled with the position on the sample from which it originated. This opens the possibility of replaying the data with a chosen lateral resolution or as a function of time to check the integrity of the sample during irradiation.

## Detectors

For the detection of X-rays lithium (Li)-drifted silicon (Si) detectors are generally used. The energy resolution of these detectors varies between 130 and 180 eV at 5.9 keV and is dependent on the size of the silicon crystal used. Large detectors have the advantage of a large solid angle at the price of resolution.

During PIXE analyses, the sample is normally surrounded by several detectors. **Figure 5** shows such a multidetector arrangement for full characterization of the specimen. Besides the Si(Li) detector for trace element determination by PIXE, an SBD placed backwards records the RBS spectrum. This is used to determine the matrix composition so that matrix correction can be calculated. A germanium (Ge) detector measures  $\gamma$ -radiation emitted by light sample nuclei, such as boron, fluorine, and sodium, thus providing additional information about elements not detected by the Si(Li) detector. In conventional PIXE setups, the X-rays of these light elements are absorbed in the detector window (usually 25  $\mu\text{m}$  beryllium); thinner windows are not used in such devices because protons scattered from the sample must be prevented from entering the Si(Li) detector. Still, PIXE is also a good tool for light element analysis due to its high cross-sections in the region of low atomic numbers. The technical difficulties caused at low  $Z$ -s by X-ray absorption in detector window and the presence of scattered bombarding particles entering the detector can be circumvented by the application of an X-ray detector of ultrathin ( $\sim 300$  nm) window (UTW) and a permanent magnetic circuit acting as a magnetic deflection trap, respectively. With the combined application of UTW and Be-windowed Si(Li) detectors in recent PIXE systems, complete analytical characterization of elemental constituents from carbon to uranium is possible in a single irradiation process.

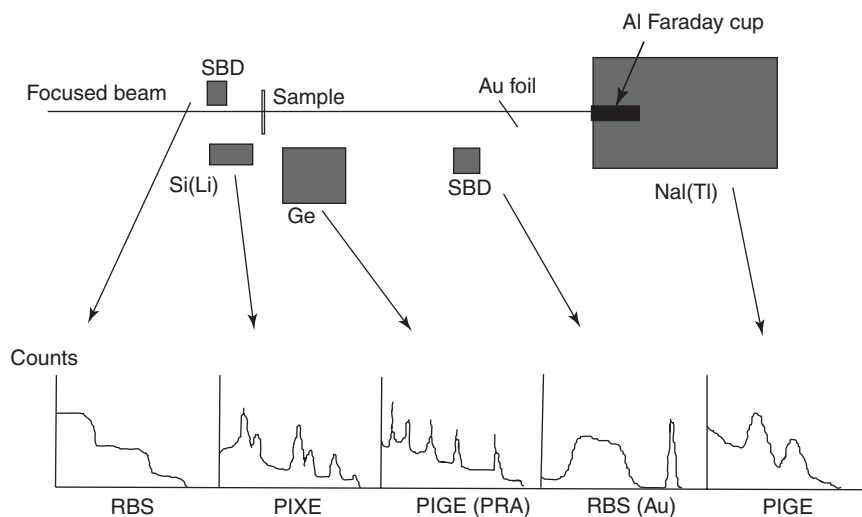

Several methods can be used to monitor the target thickness of specimens that are transparent to the beam. In **Figure 5**, protons transmitted by the sample are scattered off a thin gold foil and recorded with a second SBD. This is an elegant procedure since the accumulated charge is measured by the area of the gold peak and the target thickness by the energy of that peak. Finally, a thallium-doped sodium iodide well-type scintillator envelops an aluminum Faraday cup in which  $\gamma$ -radiation originating from inelastic scattering on aluminum is used for monitoring the beam intensity and stability.

## Applications

Macro- and micro-PIXE find applications in different types of analytical work.

**Figure 4** Schematic view of a specimen chamber used for micro-PIXE. Only two detectors are indicated – a Si(Li) for PIXE and a SBD for RBS.

**Figure 5** A multidetector setup used in combination with a nuclear microprobe. Types of spectra obtained are indicated. PIGE, particle-induced  $\gamma$ -ray emission; and PRA, prompt radiation analysis. See text for further explanation.

### Macro-PIXE

From the earliest days of PIXE, biological applications have attracted much attention. The role of essential trace elements and correlations between the concentrations of these elements and different types of diseases have been widely studied. The more recent interest in environmental problems led to an increase in the use of PIXE. Since PIXE is an almost ideal technique for the multielement analysis of aerosols filtered out of the atmosphere, many

laboratories embarked into programs on environmental pollution. The filters or other collection surfaces from various types of samplers can be placed in the beam without any pretreatment, and the subsequent PIXE analysis can be done very quickly and, if necessary, can be fully automated in order to obtain large datasets that are of statistical significance. To an increasing extent, geological and archaeological samples have been analyzed by PIXE, including objects of art. However, other analytical techniques have been refined to give better detection limits,

higher accuracy, etc., and therefore macro-PIXE now has a number of serious competitors. Contrary to the earlier broad scope of biological applications of PIXE, biologists will nowadays very often use in-house equipment based on competitive methods for their analytical needs. These have made the biological applications of PIXE less attractive than in the early days. Present-day biological applications of PIXE are concentrated on cases, where its advantage of being able to perform a full microelemental analysis on a very small amount of sample material (mg) is of primary importance. The majority of biological and biomedical applications is based on the micro-PIXE technique. As an illustration of biological work, Figure 6 shows a PIXE spectrum for the former NBS 1571 orchard leaves standard reference material, together with an indication of the elements and their concentrations. The nondestructive nature of PIXE means that there is no need for laborious destruction of the specimens. This is very important in a number of fields, among others in studying geological and archaeological samples.

PIXE finds special fields of applications in geological investigations. Of special interest is the study of the contribution of arid regions to the global aerosol burden. PIXE analyses performed on volcanic samples from the neighborhood of a volcano and from its emission plume contribute to a more complete characterization of the processes governing the eruption in its different phases. The method finds applications in research in mineralogy and petrology, geogas analysis, as well in prospecting for raw material. As possible fields of PIXE applications measuring

sea-air exchange of materials, dating of ice cores in ice sheets can also be mentioned.

Aerosol work remains a major and convincing application of macro-PIXE. Many PIXE workers are nowadays specialists in aerosol physics and chemistry. The method plays a role in global and regional air quality monitoring through time dependent and sequential measurements of aerosol, in the separation of natural and anthropogenic components, and in source apportionment. Low trace element detection limits make the method applicable in studying aging and transformation of primary aerosols together with transport and deposition phenomena. Regional signatures deduced from PIXE datasets can be used as tracers in following long-range transport tracks over thousands of kilometers.

In environmental problems PIXE finds applications in acid-rain investigations, river water analysis, monitoring the deposition of marine and lake sediments, and the mixing of salt and fresh water in coastal regions. Location and qualification of sources contaminating soils and agricultural products can be performed with PIXE analysis. It is a versatile tool both in fundamental research on the processes in the respiratory tracts and in respiratory health survey aiming at guaranteed occupational safety in work environment.

Research in art and archeology uses PIXE as an analytical tool in the fields of early development of pottery, metallurgy, and glassmaking, in numismatics, in studying painting material and color additives, paper-like objects and manuscripts, and in provenance studies of artifacts.

**Figure 6** The PIXE spectrum of orchard leaves (NBS 1571), showing the concentrations measured ( $\mu\text{g/g}$ , unless indicated otherwise).  $E_p = 3.0$  MeV;  $I = 42$  nA;  $t = 2350$  s; absorber =  $200\ \mu\text{m}$  PTFE. ### Micro-PIXE

The development of nuclear microprobes brought about a strong revival of PIXE as an analytical method. The capability of PIXE to analyze on a micrometer scale at trace levels in a quantitative way has meant that there is little competition. Moreover, as mentioned before, the combination of methods possible with a megaelectronvolt ion beam focused down to  $<1\mu\text{m}$  offers unique analytical possibilities.

In biology, the ability to measure at the cellular level, as has been shown in an increasing number of papers, finds recent interest. The production of elemental maps for biological sections of both hard and soft tissues has provided new information about the role of essential trace elements and on biological processes like metal uptake by microorganisms, the appearance of elemental gradients across membranes, matter exchange between symbiotic partners, physiological functions and root structure of plants. As an example, in **Figure 7**, elemental maps

**Figure 7** Micro-PIXE elemental maps for the distribution of C, O, Na, Mg, Si, P, S, K, and Fe in root of plant rape (*Brassica napus*) (size of scanned area:  $500 \times 500\mu\text{m}$ ). (Reproduced with permission from Kertész Zs, Uzonyi I, and Kiss ÁZ (2003).)

taken in the Debrecen (Hungary) micro-PIXE beam-line on root sections of heavy metal accumulating rape plant (*Brassica napus*) are shown. The combined use of UTW and Be-windowed X-ray detectors made the mapping of elements of low atomic number such as C, O, Na, Mg together with higher Z elements Si, P, S, K, Fe shown here also possible. In the biomedical field hair has been studied extensively with micro-PIXE in order to find correlations between trace elements in hair and blood or tissue; radial scans across a single hair can distinguish between the different routes followed during the incorporation of trace elements in hair, including environmental exposure. Longitudinal scans, on the other hand, provide information in time. Light can be thrown on the role of trace elements in physiological and pathological processes on a cellular scale. Degeneration mechanisms in aging process, structural changes in calcified tissues, and wearing processes in oral and orthopedic implants can be followed by micro-PIXE measurements, as well.

Aerosol work has also profited from micro-PIXE, as single particle analysis has become feasible. Accurate correlation between the chemical composition of such particles and their size and shape provides information about the sources of the particles and about the transformations that take place during atmospheric transport. In other environmental studies, micro-PIXE has been used to measure the uptake of trace elements in plants, roots, and trees. In particular, tree rings, which also record time information, have been analyzed in several laboratories.

In materials science, micro-PIXE is used, among other applications, in microelectronics analysis, to study insulating materials, binary alloys, surface layers, and multilayers, in locating dopant atoms in crystals through PIXE channeling, to monitor the homogeneity of ceramic superconducting materials, to study segregation in metals, and to analyze the presence and distribution of trace metals in polymers. Catalysts are also studied with micro-PIXE, in particular the diffusion of the catalytically active metal species into the supporting material. The analysis of impurities deposited on the walls of nuclear fusion devices can be mentioned as a special field of applications, too.

In geology, there is such a wide variety of applications that a few laboratories with a microprobe use their accelerator exclusively for this type of research. Fundamental geological studies, not only work on fluid inclusions, zonation in several minerals, etc., but also the search for precious metals in ores, are issues amenable to micro-PIXE. Extraterrestrial material has also been investigated with the nuclear microprobe. The lateral resolution and the

multielement character of micro-PIXE offer new information for cosmology and cosmochemistry on the composition and morphology of meteorites and cosmic dust, on origin of microspherules, and on trace element constituents in lunar rocks. Scans across typical inclusions, called chondrules, in ordinary chondrites, a class of stony meteorites, reveal the distribution of trace elements. A study of the distribution may shed light on the cooling history and sequence of solidification of minerals in such objects. As an example, **Figure 8** gives the results of a line scan over a chondrule. Zinc is the element of interest in this instance. Zinc is a volatile element and is present in such a low concentration that only spot measurements are done. The distribution of the major element silicon is also given in **Figure 8**. The micrograph shows the scan, made visible after the measurements by deposition of carbon. The chondrule can be seen on the right-hand side. The results clearly show a depletion of zinc in the chondrule as compared with the surrounding matrix.

Micro-PIXE offers a powerful nondestructive analytical method of micrometer-scale lateral resolution for research in art and archeology. Among other fields of application studies in corrosion processes, searching for characteristic features of painting and fabrication techniques, identification of art objects through trace element qualifications, and testing of restoration methods can be mentioned here.

In addition to the applications mentioned above, a wide variety of lesser activities in all branches of science are studied using PIXE. In all cases where it is beneficial to use a trace element analytical technique that combines a lateral resolution of  $\sim 1\text{ }\mu\text{m}$  with trace element detection limits ( $1\text{--}10\text{ }\mu\text{g g}^{-1} \equiv 10^{-15}\text{--}10^{-16}\text{ g}$ ), micro-PIXE is an option well worth considering.

## PIXE for Surface Analysis

As stated above, PIXE is surface sensitive in the sense that the limited range of the incoming ions and the decrease of the contribution to the analytical signal from deeper layers means that most information originates from the outermost  $10\text{ }\mu\text{m}$ . Nevertheless, the examples of applications given above are not real examples of the analysis of the very surface (outermost atomic layers) or of an interface. In contrast to the resonances in the cross-sections for nuclear reactions, which are therefore used for high-resolution depth profiling within the range of the bombarding particles, PIXE cross-sections have a smooth behavior with depth. Still, special deconvolution algorithms to be applied on a series of experiments with incident

**Figure 8** Results of a line scan over the matrix–chondrule interface shown in the micrograph (C). The chondrule is the whitish area on the right-hand side. The scan is visible as a black mark because of carbon deposition and was 0.55 mm long. Results are given for zinc (A) and silicon (B). Only spot measurements were feasible for zinc because of the low concentration present.

bombarding energies, varied over the appropriate energy interval, offer a technique for deducing depth distribution curves of the elements detected in PIXE spectra. PIXE's high sensitivity, however, enables

detection of very small contaminations or a very thin surface layer (a few atomic layers) on a suitable substrate, especially if the analyte has a higher  $Z$  value than the substrate. Heavier incident particles are even more

suitable here because of their much higher stopping power.

Even higher sensitivity is obtained if the ion beam impinges on the specimen at a glancing angle. This lengthens the path traveled through the surface layer of interest and also decreases the bremsstrahlung background owing to reflection of ions at the surface, resulting in lower production of secondary electrons. PIXE used in this mode is a true surface technique but a price is paid in terms of reduced lateral resolution because of the small angle between the beam and the target surface.

Other developments include improvements in detector technique to such an extent that, besides information about the elemental composition, chemical information also become available. The replacement of commonly used energy-dispersive Si(Li) X-ray spectrometer with high-resolution wavelength dispersive bent crystal spectrometer in combination with proportional counters opens a new field of applications for PIXE by resolving the pattern of satellite lines that is dependent on the chemical environment of the analyte atom. In such investigations beams of multiple charged light heavy ions are preferentially used. The underlying physical processes and the quantitative features of the fine structures in the spectra to be used in chemical state analysis are the subjects of recent investigations. Instrumental improvements aim towards sub-micrometer lateral resolution with appropriate beam intensity. The fact that, unlike electrons, incoming ions show virtually no scatter away from their path through the specimens helps in maintaining this extreme lateral resolution during real analyses.

This article is a revision of the previous-edition article by G E McGuire, pp. 4907–4912, © 1995, Elsevier Ltd.

## Introduction

The Auger electron emission phenomenon was revealed by P. Auger in 1925 when he observed

nonradiative relaxation of excited ions in a cloud chamber. L.A. Harris observed Auger electron emission examining solid surfaces in 1968. Since then the spectroscopic method utilizing Auger electron emission has developed rapidly and is in widespread use today. In this review of Auger electron spectroscopy (AES), the basic principles of the technique will be described, a description of a modern instrument will be given, examples of modes and applications of AES will be provided, and trends in the use of AES in surface and thin film analysis will be reviewed.

## Basic Principles and Qualitative Surface Analysis

Focused electron beams are the primary means of stimulating Auger electron emission, although, other energetic beams, e.g., X-ray photons or ions, may also be used. **Figure 1** is a schematic diagram of the Auger emission process in a metal. When an electron beam of energy,  $E_P$ , much greater than core electron binding energies of the solid,  $E_K$ , impinges on the surface, ionization occurs as depicted in the left panel of the figure due to hole formation in a core level, here the K shell. The atom is left in an excited state which decays radiatively or nonradiatively by emission of X-rays or Auger electrons, respectively. **Figure 1** shows an electron from the  $L_1$  level filling the hole created in the K shell while a second electron, the Auger electron with the kinetic energy  $E_A$ , is emitted from the  $L_{2,3}^*$  level. This results in a doubly ionized state shown in the right-hand panel of **Figure 1**. Various combinations of the discrete core levels and also valence band electrons may enter into this three-electron process resulting in series of Auger transitions with various energies characteristic of the emitter element. These are tabulated in databases, denominated, e.g., as KLL, LMM or MNN series, and often displayed in a table as in **Figure 2**. The competing X-ray emission (radiative core hole decay) influences the relative probability of relaxation by Auger electron emission.

The kinetic energy of the ejected Auger electron illustrated in **Figure 1** is

$$E_{KL_1L_{2,3}} = E_K - E_{L_1} - E_{L_{2,3}}^* - \Phi_A \quad [1]$$

where  $E_K$  and  $E_{L_1}$  are the binding energies of the atomic energy levels K and  $L_1$ .  $E_{L_{2,3}}^*$  is the binding energy of the  $L_{2,3}$  level in the ion and, therefore, different from  $E_{L_{2,3}}$  for the ground state of the emitter atom.  $\Phi_A$  is the work function of the energy analyzer.

The kinetic energy of an Auger electron is characteristic for the atomic levels and, hence, for a given element, qualitative elemental analysis is enabled. Chemical shifts, similar to those observed in X-ray photoemission, may occur due to initial effects (chemical bonding) or final state effects (intra- and extra-atomic relaxation). Thus chemical bonding frequently influences the fine structure of a series of Auger transitions and the resulting chemical shifts of their kinetic energies can be utilized to derive chemical state information on the emitter atom. **Figure 3** shows highly resolved Si Auger KLL spectra of metallic Si, SiN, and SiO<sub>2</sub>, illustrating the dramatic changes of peak shapes and positions in the Auger spectrum of Si upon compound formation.

There are popular databases and handbooks that provide characteristic Auger electron spectra, beginning with lithium and ending with uranium. These spectra were obtained under controlled

**Figure 1** Schematic diagram of the Auger emission process using electron beam excitation.

**Figure 2** Survey of the most useful Auger transitions for all elements in the periodic table. Black diamonds indicate the strongest peaks usually used in practical AES applications. Gray bands indicate the kinetic energies of less intense peaks. (Reprinted from [www.eaglabs.com](http://www.eaglabs.com) with permission of the Evans Analytical Group.)

conditions. They can be used for chemical state identification by AES.

Because AES is a method of surface analysis its information depth should be considered. **Figure 4** contains the relevant information. The incident electron beam striking the specimen penetrates to a

depth of 1–3  $\mu\text{m}$ , depending on its initial kinetic energy and inelastic scattering in the solid. Within the primary excitation volume a variety of elastic and inelastic processes occur. Auger emission will occur within this volume until the energy of inelastically scattered electron falls below the threshold energy

for ionization. However, most of the secondary electrons, including the Auger and photoelectrons, never reach the surface because of their very short inelastic mean free paths. Figure 5 shows the principal dependence of the electron inelastic mean free path,  $\lambda$ , on the electron energy. Therefore, in the energy range of interest in AES, from 0 to 2000 eV, the information depth is in the range of 0.5–7.5 nm, i.e., only a few monolayers, depending on the material analyzed and the individual Auger transition used.

## Quantitative Surface Analysis

There is a well-founded understanding of the correlation of a measured Auger electron intensity with

the concentration of the respective emitter atom in a solid sample. Basic parameters involved are:

- primary electron beam current and energy;
- elemental core hole ionization cross-sections as a function of the primary electron beam energy;
- Auger transition probability;
- probability of core ionization by energetic electrons scattered in the solid (so-called backscatter effect) characteristic of the material;
- inelastic mean free path,  $\lambda$ , depending on the Auger electron energy and the material;

**Figure 3** Highly resolved Si KLL Auger transitions of silicon dioxide (dashed line), silicon nitride (solid line), and zero-valent silicon (dotted line). (Reproduced with permission from ULVAC-PHI.)

**Figure 5** Electron inelastic mean free path,  $\lambda$ , versus kinetic energy of (Auger) electrons. (Reproduced with permission from Seah MP and Dench WA (1979) *Surface and Interface Analysis*, vol. 1, 4p. Wiley, © Wiley.)

**Figure 4** Primary excitation volume and escape depth for Auger electrons. (Reproduced with permission from ULVAC-PHI.)

- spectrometer function (analyzer transmission, detector efficiency, geometry of the experiment, etc.).

Matrix effects, which are somewhat stronger in comparison to those in quantitative X-ray photoelectron spectroscopy, mostly originate from the backscatter effect. Many of the parameters mentioned above are difficult to determine. Therefore, in practical quantitative AES empirical relative sensitivity factors (RSFs) are used and the concentration  $C_i$  (at%) of element  $i$  in the thin AES analytical volume is derived for a certain matrix from measurements of the intensities measured for element  $i$ ,  $I_i$ , and all elemental constituents  $j$  by

$$C_i = 100 \text{RSF}_i I_i / [\sum_j (\text{RSF}_j I_j)] \quad [2]$$

Matrix effects are thus 'embedded' in the RSFs. There are RSFs for elements and selected matrices (compounds) published in the literature. Certified reference materials are very useful to obtain reliable RSFs. However, sample homogeneity is required for application of eqn [2]. The primary electron beam diameter must be narrower than the scale of lateral heterogeneity. Heterogeneity of the analytical volume in depth is also crucial. Here, special quantitative models were developed by different authors.

The detection limits of quantitative AES are in the range of 1–0.01 at% depending on the element and the matrix under consideration.

## Instrumentation

A variety of electrostatic analyzers are used as electron spectrometers. The cylindrical mirror analyzer is the one most frequently used in AES because of its combined excellent energy resolution and high transmission efficiency. A schematic diagram of a recent Auger spectrometer design is shown in Figure 6. The cylinders of the analyzer are arranged coaxially; the inner cylinder is at ground potential while the outer cylinder is held at a negative potential. Electrons emitted from the analyzed sample enter the zone between the cylinders through an aperture and are deflected by the negative potential on the outer cylinder. By sweeping the potential on the outer cylinder, Auger electrons of varying energy can pass through the analyzer.

The primary electron gun, electron optical devices, deflection plates and the micro channel plate Auger electron detector are mounted coaxially with the cylinders of the analyzer. The focal point of the analyzer is coincident with the focal point of the primary electron beam. Scanning Auger microscopy (SAM) is

**Figure 6** Schematic diagram of a recent Auger electron spectrometer design. (Reprinted from [www.eaglabs.com](http://www.eaglabs.com) with permission of the Evans Analytical Group.)

enabled by using the deflection plates which direct the primary electron beam across the analysed surface. Modern instruments use high-brightness field emission primary electron guns operated at up to 25 keV. Beam diameters less than 10 nm are achievable. Usually, Auger spectrometers are equipped with a secondary electron detector, which additionally allows secondary electron imaging.

Another standard component is an ion gun providing ions which may impinge on a defined sample position seen by the Auger electron analyzer. The ions gradually erode the sample surface so that when combined with the surface analysis intrinsic to AES an elemental in-depth profile is obtained from a well-defined small area of the sample. Inert gases, such as argon, are typically used so that the ions do not react with the sample surface. The erosion rate is material dependent but can be 50–100 nm min<sup>-1</sup>.

It should be mentioned here that AES must be carried out under ultrahigh vacuum conditions. Samples to be measured must be compatible to this and stable under energetic electron irradiation.

Sample charging is a frequent problem encountered in the analysis of insulators by AES. Any surface charging will distort the Auger signal intensity and shape as well shift the spectrum rendering the analysis meaningless. Charging may also occur for conductive material embedded in insulating surroundings. It has been shown that a positive low-energy argon ion beam can be successfully used to neutralize the surface charge. Ion current and energy as well as the irradiated area are the critical parameters here.

## Applications

AES is sufficiently mature and its application broad. Many general reviews of the technique deal with specific applications in general surface and thin film analysis. AES is often used to solve problems in metallurgy, plating, corrosion, and catalysis. Reviews covering these applications are listed in the Further Reading section. Because the primary electron beam can be focused down to a diameter of less than 10 nm, information about local compositions on a specimen's surface can be obtained. This special feature makes AES very attractive for applications in the semiconductor technology where submicrometer features are of interest. To satisfy semiconductor manufacturers, AES systems that are able to handle 300 mm silicon wafers are commercially available now.

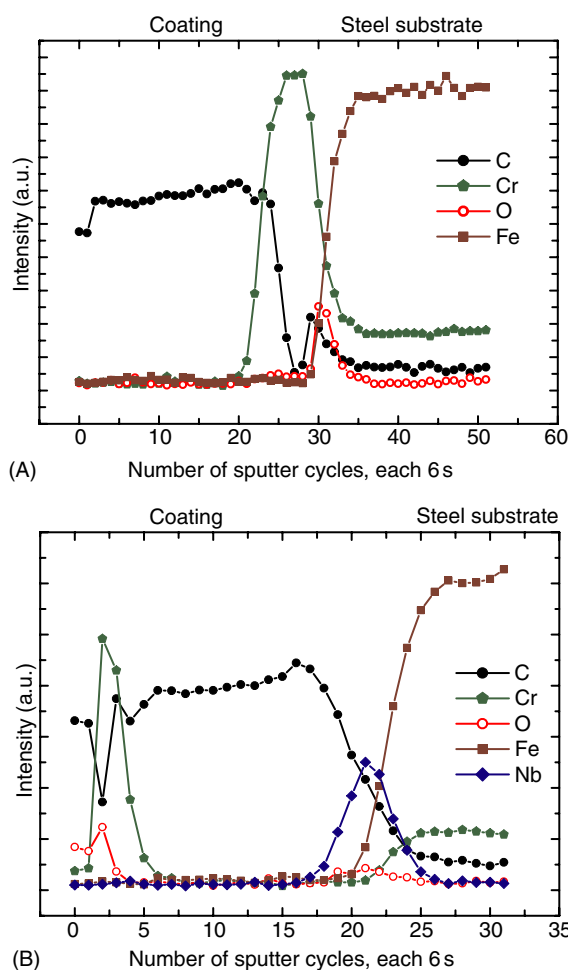

There are different modes of application of AES: (1) spectroscopy, also for rather small areas, (2) depth profiling, and (3) element mapping.

Considering the spectroscopic mode, a typical survey scan covers the range from 0 to 2000 eV of kinetic energy. Since there are characteristic kinetic energies of Auger transition series, i.e., KLL, LMM, and MNN, elemental identification for elements with  $Z \geq 3$  is excellent and quantification is possible. The Auger yield of the characteristic Auger transition series decreases, in competition with X-ray emission, as a function of increasing atomic number. However, there is always at least one intense Auger transition available for characterization. Since AES makes use of a focused electron beam for excitation, high spatial resolution is achieved. This permits analysis of, e.g., particles, residues, corrosion products, and adsorbed contaminants that may be nonuniformly dispersed over the surface. As mentioned earlier, Auger spectra contain a bounty of chemical information. To derive this, the spectroscopy mode has to be used at high-energy resolution. Historically, Auger data was taken in the derivative mode and plotted as  $d(N(E) \times E)/dE$  versus kinetic energy. In this mode, the peak minima were used to characterize the transition and the peak shape was frequently used as fingerprint of the chemical oxidation state. **Figure 7A** displays the changes of the Ti  $L_{3}M_{23}V$   $d(N(E) \times E)/dE$  spectrum depending on the chemical state of Ti. **Figure 7B** shows the Si KLL  $d(N(E) \times E)/dE$  spectra of  $\text{SiO}_2$  which can be compared to the respective  $N(E)$  spectrum given in **Figure 3**. Modern instruments collect the data in the  $N(E) \times E$  or  $N(E)$  mode (providing outputs as displayed in **Figure 3**) and electronically take the derivative when desirable. In any case  $N(E) \times E$  or  $N(E)$  spectra are better suited for quantification.

**Figure 7** (A) Ti  $L_{3}M_{23}V$   $d(N(E) \times E)/dE$  Auger spectra of a Ti surface oxide, TiN, and metallic Ti. (B) Si KLL  $d(N(E) \times E)/dE$  Auger spectra of silicon dioxide. (Reproduced with permission from ULVAC-PHI.)

Surface analysis by itself is rarely sufficient to characterize a sample. Sputter depth profiling in combination with surface analysis by AES is essential in order to characterize a sample thoroughly. **Figures 8A** and **8B** illustrates the insight that may be obtained for different tribological coatings on a steel substrate. By monitoring the C, Cr, Nb, O, and Fe Auger transitions as function of sputtering time, the in-depth composition of the coating was determined. After the initial surface contamination was removed by sputtering, a layer of  $\sim 50$  nm of carbon originating from a diamond-like carbon (DLC) layer was observed (**Figure 8A**). The DLC layer was

**Figure 8** (A) AES depth profile of steel substrate plated with a Cr interlayer and a diamond-like carbon layer using stepwise sputter erosion of the sample. (B) AES depth profile of steel substrate plated with an Nb interlayer, a diamond-like carbon layer, and a thin Cr top layer using stepwise sputter erosion of the sample. (Reproduced with permission from ULVAC-PHI.)

deposited on the steel substrate, which is represented by Fe and Cr Auger transitions, using a Cr interlayer of  $\sim 5$  nm to promote adhesion. The small C and O peaks between the Cr interlayer and the steel substrate point to some contamination of the steel substrate before coating. **Figure 8B** displays results obtained with a more complex system. Here a very thin Cr top coating on a thicker DLC layer was found and the adhesion promoting interlayer was made of Nb.

The primary result of an AES depth profile analysis is an Auger transition intensity versus sputter time presentation. Quantification leading to atomic concentrations is possible when RSFs or reference materials are available. A measurement of sputter rates which depend on the sputtered material enables

changing of the sputter time scale into a depth scale. However, because the effort required to determine reliable RSFs and sputter rates for an individual sample is rather high, often the Auger transition intensity versus sputter time representation of depth profiles is successfully used to compare related samples.

The third mode in which Auger data may be taken is the AES mode called scanning Auger microscopy, or SAM. Since the electron beam can be focused to a rather small spot, AES may be used to analyze localized features of a sample surface. This is accomplished in AES by rastering the electron beam over the area being analyzed while synchronously detecting the Auger signal. This is usually done by setting the analyzer transmission so that electrons of a specific energy reach the detector. Elemental distribution maps for different elements must be obtained sequentially. The distribution of compounds or elements in a certain oxidation state may be mapped when a chemically shifted peak is available for analysis. **Figure 9** shows the secondary electron micrograph of a 'flower defect' on a silicon wafer with low contrast because the petal-shaped residue is only 1–2 nm thick. SAM is the only method to detect such a thin contamination because of its unique spatial resolution and surface sensitivity. An accompanying overlay of Si, Al, and C AES maps as well as an individual F AES map is also given in **Figure 9**. These elemental maps reveal that the defect comprises a submicrometer scaled central particle with Al as a constituent and a fluorocarbon contaminant petal surrounding it.

## Quality Assurance in AES

One critical aspect of the reliable application of AES in research and technology by warranted quality of analytical results is the establishment of reference data, reference materials, reference procedures and, finally, written international standards. There are different bodies involved in this work.

At first the Versailles Project on Advanced Materials and Standards (VAMAS) to support international trade through projects aimed at providing the technical basis for drafting codes or practice and specifications in advanced materials should be mentioned here. The VAMAS Technical Working Area (TWA) 2 'Surface Chemical Analysis' has the production of reference procedures, data, and materials for surface chemical analysis as its objectives. Rather important interlaboratory comparisons were organized as part of VAMAS TWA2 projects. A survey of working and finalized TWA2 projects as well as

**Figure 9** Secondary electron image (upper left) and Auger elemental maps of C, Al, Si, and F of silicon wafer contamination comprising an Al central particle with fluorocarbon petals. (Reproduced with permission of ULVAC-PHI.)

related publications and reports is given at <http://www.vamas.org>.

The ISO Technical Committee 201 'Surface Chemical Analysis', the second body that is active in this area, is dedicated to the standardization in the field of surface chemical analysis in which beams of electrons, ions, neutral atoms or molecules, or photons are incident on the specimen material and scattered or emitted electrons, ions, neutral atoms or molecules, or photons are detected. Valid ISO standards on surface chemical analysis with relevance to AES are (January 2004, see ISO TC 201 at <http://www.iso.ch>):

- ISO 14606 Sputter depth profiling – optimization using layered systems as reference materials;
- ISO 14975 Information formats;
- ISO 14976 Data transfer format;
- ISO/TR 15969 Depth profiling – measurement of sputtered depth;
- ISO 17973/17974 – Medium-resolution/high-resolution Auger electron spectrometers – calibration of energy scales for elemental analysis;
- ISO 18115 Vocabulary;
- ISO/TR 19319 Auger electron spectroscopy – determination of lateral resolution, analysis area, and sample area viewed by the analyzer.

Moreover, there are a number of AES-related ISO standards under development. They are dedicated to the description of selected instrumental performance parameters (DIS 15471), specimen handling (CD

18116 and 18117), use of experimentally determined relative sensitivity factors for the quantitative analysis of homogeneous materials (CD 18118), derivation of chemical information (AWI 18394), determination of lateral resolution (WD 18516), peak intensity determination (WD 20903), linearity of intensity scale of AES spectrometers (PRF 21270), peak detection methods to perform qualitative or quantitative analysis (WI 22474), and repeatability and constancy of the intensity scale of AES spectrometers (D 24236).

The American Society for Testing and Materials Committee E-42 on Surface Analysis (<http://www.astm.org>), as a third body, continues to be active in developing standards. E-42 members have developed a Standard Terminology (E673-02b), as well as AES-related Standard practices and Standard Guides on the identification of elements (E827-02), minimizing unwanted electron beam effects (E983-94), identifying chemical effects and matrix effects (E984-95), background subtraction (E995-97), reporting data (E996-94), depth profiling (E1127-03), determination of current density of ion beams for sputter depth profiling (E684-95), and reporting ion beam parameters (E1577-95).

As a result, AES as an analytical method can be viewed to be sufficiently mature and the level of standardization reached now allows the preparation of standard operation procedures (SOPs) for its application. Thus, an integration of AES into practical quality management systems following ISO 17025 is possible and today there is a number

of accredited testing laboratories running SOPs using AES.

## Introduction

The structural and electronic properties of the top few atomic layers of metals and semiconductors play a dominant role in the chemical (catalysis, corrosion) and electronic (semiconductor device interface) properties of a range of materials. For the study of electronic structure, surface analytical techniques typically employ particles such as photons, electrons, atoms, molecules, or ions. These particles must have just enough energy to probe only a few tenths of a nanometer into the solid, thereby investigating the surface atoms rather than the bulk atoms. Since low-energy electrons have inelastic mean free paths of only a few tenths of a nanometer in solids, they are made use of in many techniques, either as the incident projectile or as a particle emitted from the surface region.

The distribution of the energy states (density of states, DOS) in the vicinity of the Fermi level,  $E_F$  (the highest energy occupied level), forms the valence (occupied states) and conduction (unoccupied states) bands of solids. The technique employed for the study of the electronic structure of surfaces, therefore, fall broadly into two groups: techniques that investigate the occupied DOS (such as X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES)) and those that investigate the unoccupied density of states (e.g., X-ray absorption spectroscopy (XAS), inverse photoemission (IPE), Bremsstrahlung isochromat spectroscopy (BIS), and

appearance potential spectroscopy (APS)). This article discusses the different techniques that explore the conduction band states, concentrating on the various aspects of APS that apply to surface characterization of materials.

In XAS, the incident X-rays traverse through the sample. X-rays of appropriate energy are absorbed by the atoms and as a result a core electron is excited to unoccupied states above  $E_F$ . The decrease in the transmitted X-ray intensity is measured. In this spectroscopy, selection rules are rigorously obeyed and therefore the DOS of all symmetries must be considered to understand completely the electronic structure of the conduction band. The schematic of this X-ray excitation of a core level atom, in the one-electron approximation, is shown in **Figure 1**. In the one-electron approximation, the activity of one electron is considered at any instant, assuming all other electrons to be fixed. Because the incident X-rays traverse the whole sample, little surface information is obtained.

In BIS, the sample to be investigated serves as the anode of an X-ray tube. An X-ray spectrometer is tuned to detect X-rays of certain definite energy,  $\hbar\omega_0$ , which is arbitrarily selected from the Bremsstrahlung spectrum ( $\hbar$  is  $h/2\pi$ , where  $h$  is Planck's constant and  $\omega_0$  is the selected angular frequency). As the accelerating energy  $E$  across the X-ray tube is slowly varied from just below to just above the threshold energy  $\hbar\omega_0$ , the observed intensity begins to rise and then shows structure. The curve of change in intensity for one fixed energy  $\hbar\omega_0$  as a function of incident electron energy in such an experiment is called an isochromat. The electrons with initial energy  $E(E \geq \hbar\omega_0)$ , which undergo radiative transitions emitting photons of energy  $\hbar\omega_0$  will then occupy

of accredited testing laboratories running SOPs using AES.

## Introduction

The structural and electronic properties of the top few atomic layers of metals and semiconductors play a dominant role in the chemical (catalysis, corrosion) and electronic (semiconductor device interface) properties of a range of materials. For the study of electronic structure, surface analytical techniques typically employ particles such as photons, electrons, atoms, molecules, or ions. These particles must have just enough energy to probe only a few tenths of a nanometer into the solid, thereby investigating the surface atoms rather than the bulk atoms. Since low-energy electrons have inelastic mean free paths of only a few tenths of a nanometer in solids, they are made use of in many techniques, either as the incident projectile or as a particle emitted from the surface region.

The distribution of the energy states (density of states, DOS) in the vicinity of the Fermi level,  $E_F$  (the highest energy occupied level), forms the valence (occupied states) and conduction (unoccupied states) bands of solids. The technique employed for the study of the electronic structure of surfaces, therefore, fall broadly into two groups: techniques that investigate the occupied DOS (such as X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES)) and those that investigate the unoccupied density of states (e.g., X-ray absorption spectroscopy (XAS), inverse photoemission (IPE), Bremsstrahlung isochromat spectroscopy (BIS), and

appearance potential spectroscopy (APS)). This article discusses the different techniques that explore the conduction band states, concentrating on the various aspects of APS that apply to surface characterization of materials.

In XAS, the incident X-rays traverse through the sample. X-rays of appropriate energy are absorbed by the atoms and as a result a core electron is excited to unoccupied states above  $E_F$ . The decrease in the transmitted X-ray intensity is measured. In this spectroscopy, selection rules are rigorously obeyed and therefore the DOS of all symmetries must be considered to understand completely the electronic structure of the conduction band. The schematic of this X-ray excitation of a core level atom, in the one-electron approximation, is shown in **Figure 1**. In the one-electron approximation, the activity of one electron is considered at any instant, assuming all other electrons to be fixed. Because the incident X-rays traverse the whole sample, little surface information is obtained.

In BIS, the sample to be investigated serves as the anode of an X-ray tube. An X-ray spectrometer is tuned to detect X-rays of certain definite energy,  $\hbar\omega_0$ , which is arbitrarily selected from the Bremsstrahlung spectrum ( $\hbar$  is  $h/2\pi$ , where  $h$  is Planck's constant and  $\omega_0$  is the selected angular frequency). As the accelerating energy  $E$  across the X-ray tube is slowly varied from just below to just above the threshold energy  $\hbar\omega_0$ , the observed intensity begins to rise and then shows structure. The curve of change in intensity for one fixed energy  $\hbar\omega_0$  as a function of incident electron energy in such an experiment is called an isochromat. The electrons with initial energy  $E(E \geq \hbar\omega_0)$ , which undergo radiative transitions emitting photons of energy  $\hbar\omega_0$  will then occupy

**Figure 1** A schematic diagram showing energy levels involved in techniques used to probe unoccupied density of states of a metal. XAS, X-ray absorption spectroscopy; BIS, Bremsstrahlung isochromat spectroscopy; IPE, inverse photoemission; DAPS, disappearance potential spectroscopy; SXAPS, soft X-ray appearance potential spectroscopy; and AEAPS, Auger electron appearance potential spectroscopy.

final states in the conduction band of the sample at an energy  $E - \hbar\omega_0$ . Assuming a constant radiative matrix element, the transition probability will be proportional to the density of unfilled states. The above-measured intensity will, therefore, provide the density of empty one-electron states. The electron transitions involved in the process are shown schematically in Figure 1.

IPE is an analog of BIS but with low-energy photon emission. It is an important and growing area in present-day surface analysis. IPE represents radiative capture of an electron by a solid surface, and is the inverse of photoemission. In IPE, the sample is bombarded by electrons with energy of only a few tens of electron volts. The technique is sensitive to the surface region because of the finite pathlength of low-energy electrons in solids. The photon energy spectrum emitted from a solid under electron bombardment contains information on the density of electronic states above  $E_F$ . The photon yield, which is extremely small, is measured dispersively by energy selection detection techniques. The curve of photon intensity as a function of  $E - \hbar\omega$  ( $\hbar\omega$  denotes the photon energy) measures the band structure above  $E_F$ . In actual isochromat mode, the energy of the detected photon  $\hbar\omega$  is held constant and the spectrum is obtained by sweeping  $E$ . The spectrum is considered to be a replica of the unoccupied DOS above  $E_F$ .

In APS, the surface of the specimen is bombarded by electrons in the 0–2000 eV range. When the energy of the incident electron equals that of a particular core level, the incident electron imparts its energy to the core level electron as a result of the inelastic collision. The system is then in an excited state and consists of a core hole and two electrons above  $E_F$  in the conduction band. The excitation is followed by radiative (X-ray fluorescence) and non-radiative (Auger electron) processes that compete for the de-excitation of the core holes. When the intensity of the emitted X-rays is measured the method is called soft X-ray APS or SXAPS. When the total current of the secondary electrons is measured the method is called Auger electron APS or AEAPS. In another mode, the current of the elastically reflected electrons is measured. The number of electrons that are scattered inelastically at the threshold energy of the core level excitation increases. They disappear from the measured current, and the method is, therefore, called disappearance potential spectroscopy or DAPS. The energy level diagram for APS is shown in Figure 1.

## Theoretical Background

APS measures the probability for electronic excitation of a core level as a function of incident electron energy. The energy of the incident electron is gradually increased, and the dependence of the total signal strength on this energy is measured. At certain energies a sudden change (increase or decrease) in the signal is observed, which corresponds to the excitation of a given energy level of the sample. The signal is extracted from the background with the help of an electronic differentiation technique, which enhances the signal-to-noise ratio. The intensity of the features in the APS spectrum at the threshold energy and above depends on the core hole excitation rate at that energy. The final state in the excitation process will consist of a core hole, an excited core electron, and the scattered incident electron. The fact that the shape of an APS feature is independent of the relaxation mechanism suggests the utilization of a non-dispersive scheme for this technique. Since neither an electron energy analyzer nor an X-ray monochromator is needed to obtain the experimental data, APS is undoubtedly the simplest method for studying the unoccupied DOS of solid surfaces. The surface sensitivity of APS is due to the short inelastic mean free path for the primary electrons in the energy range 0–2 kV. A primary electron with energy close to the threshold that experiences a characteristic energy loss upon penetrating the sample is no longer

able to excite the atoms. The depth of information is, therefore,  $\sim 10 \text{ \AA}$ .

Low-energy electrons interact with atoms by elastic collisions, by the emission of electromagnetic radiation, and by inelastic collisions. At the threshold energy of the core hole excitation a certain fraction of the incident electrons is involved in ionization. These electrons give up their energy and can, therefore, no longer produce Bremsstrahlung radiation in the sample. When the incident electron is captured by a state  $\varepsilon_1$  above  $E_F$ , the energy may be conserved by the excitation of a core electron into a state  $\varepsilon_2$  such that

$$\varepsilon_1 + \varepsilon_2 = E - E_b \quad [1]$$

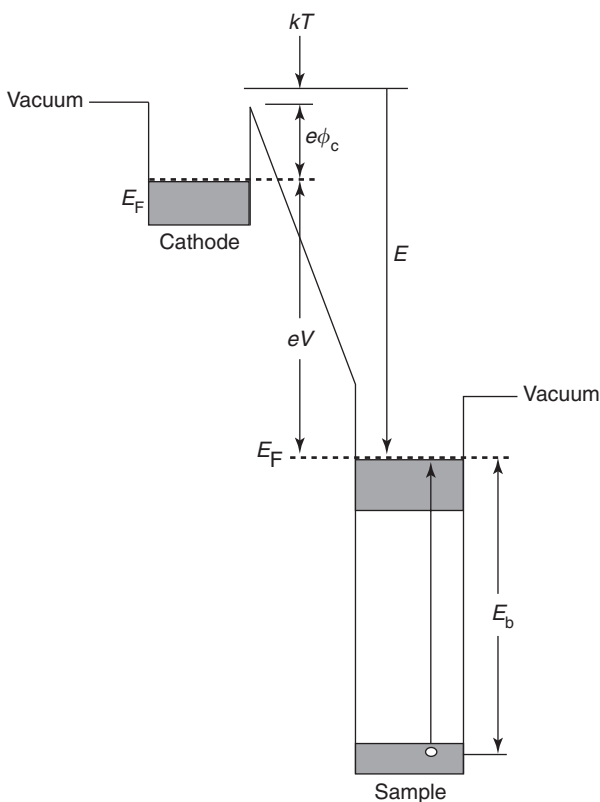

where  $E$  is the energy of the incident electron and  $E_b$  is the binding energy (BE) of a particular core level and  $E_F$  is taken as the zero of energy. The core level DOS is considered to have a negligible energy width. The incident energy is determined by  $eV + e\phi_c + kT$ , where  $V$  is the electron accelerating potential,  $e\phi_c$  is the emitter (cathode) work function, and  $kT$  is the thermal energy spread of the emitted electrons. Here,  $e$  is the charge of an electron,  $k$  is the Boltzmann constant, and  $T$  is the absolute temperature of the cathode. The final states must take into consideration all possible combinations of energies of both electrons (incident and core) that are consistent with the conservation of energy.

The characteristic emission has a distinct energy threshold (appearance potential), which occurs at  $E = E_b$  (i.e., for  $\varepsilon_1 = \varepsilon_2 = 0$ ). This results in the transfer of both the incident and core electrons to  $E_F$ , as shown in Figure 2. This event is signaled by the 'appearance' of a small bump in the total emission versus incident electron energy curve. The excitation process is the same for all APS spectra. It seems that differences in the decay step are responsible for the spectral differences between SXAPS, AEAPS, and DAPS. In terms of this model DAPS provides information directly about the excitation process and is free of the relaxation complications. SXAPS and AEAPS include additional information dependent on the different decay (relaxation) steps.

The excitation probability,  $P(E, E_b)$  of the APS process at a given incident energy  $E \geq E_b$  will be given by

$$P(E, E_b) \propto \int_0^{E-E_b} P_1(E \rightarrow \varepsilon_2) P_2(E_b \rightarrow \varepsilon_1) N(\varepsilon_1) N(\varepsilon_2) \times \delta(\varepsilon_1 + \varepsilon_2 - E + E_b) d\varepsilon_1 d\varepsilon_2 \quad [2]$$

The energy conservation is ensured by the  $\delta$  function. The factors  $P_1(E \rightarrow \varepsilon_2)$  and  $P_2(E_b \rightarrow \varepsilon_1)$ , which represent the transition probabilities, may depend on the

**Figure 2** Threshold electron excitation in APS that occurs when the incident electron energy  $E (= eV + e\phi_c + kT)$  is equal to the binding energy  $E_b$  of a core level, resulting in the transfer of both incident and core electrons to  $E_F$ . The core hole may subsequently decay by the emission of a characteristic X-ray or Auger electron.

selection rules and are not known precisely. If these factors are assumed to be constant over a small range of  $E$  values above the threshold  $E_b$ , then they can be taken as simply proportional to the DOS  $N(\varepsilon_1)$  and  $N(\varepsilon_2)$  and the equation simplifies to

$$P(E, E_b) \propto \int_0^{E-E_b} N(E - E_b - \varepsilon_2) N(\varepsilon_2) d\varepsilon_2 \quad [3]$$

which is simply the self-convolution of the density of the conduction band states.

In APS the signal is extracted from the background by modulation techniques. The resulting spectrum, therefore, represents the differential of the convoluted density of unoccupied states near  $E_F$ . The strength of the APS signal is given by

$$\text{APS}(E) \propto \int_0^{E-E_b} N(\varepsilon_2) \frac{d}{dE} N(E - E_b - \varepsilon_2) d\varepsilon_2 \quad [4]$$

Therefore, APS is particularly suitable for studying materials that have high DOS above  $E_F$ . There are

three main groups of elements that provide strong signals: 3d transition metals, alkaline earths, and rare earths. If the DOS is low or have disadvantageous character, APS cannot be utilized as a universal analytical technique. Nevertheless, APS has the potential for providing interesting results that cannot be obtained by other techniques.

The binding energies of the core level peaks are calculated from the corresponding appearance potential peaks. As core binding energies are characteristic of specific elements, chemical analysis of the surface is feasible. Since the APS yield is proportional to the self-convolution of the density of the unoccupied states broadened only by the finite lifetime of the core hole and by the finite experimental resolution, precise knowledge about the conduction band can be obtained by using deconvolution techniques. In SXAPS and AEAPS the intensity depends upon the fluorescence and Auger yields, respectively, which depend on the type of electron shell, on the binding energy, and on the local atomic environment.

As a tool for chemical analysis, APS has its merits when compared with other techniques. Electron-induced X-ray emission spectroscopy employs primary electrons of several kiloelectronvolts in most experiments, so that information originates mainly from the bulk. Since the dispersion of X-rays by monochromators presents considerable experimental problems, very little attempt has been made to study surface properties by analyzing X-ray spectra. APS, however, has the advantage that it utilizes primary electrons with energy less than  $\sim 2$  keV for the excitation of X-ray spectra; the shallow penetration depth of these electrons makes APS an attractive technique for surface analysis. AES utilizes the non-radiative process following the ionization of a core level of an atom as a tool for surface analysis. This technique employs energy analysis to determine the electronically differentiated energy distribution of the Auger electrons. AEAPS is the derivative of the total secondary emission electron current with respect to incident electron energy and gives information about the density of unoccupied states above  $E_F$ . However, the applicability of AEAPS as an analytical tool for determining the surface composition in a manner similar to AES is limited, since AEAPS is quite insensitive to a number of elements. In XPS, the principle of the experiment is to measure the kinetic energies  $E_{kin}$  of photoelectrons liberated from their bound states with energies  $E_b$  by interaction with monochromatic X-rays of energy  $h\omega$  and is given by

$$E_{kin} = h\omega - E_b \quad [5]$$

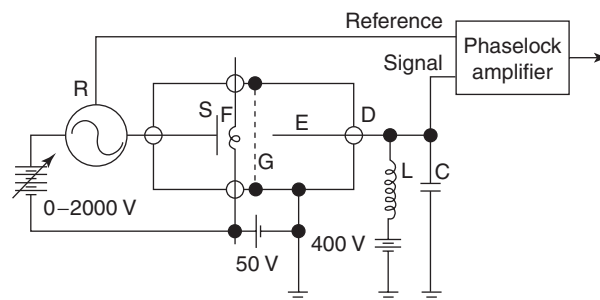

Soft X-ray sources with energies in the range of  $\sim 1$  keV are used, which makes the technique

sensitive to the surface properties of materials. XPS is suitable for studying the occupied DOS and the chemical shifts in the core electron-binding energies. In this respect, APS, AES, and XPS are complementary techniques.

## Experimental: Soft X-Ray Appearance Potential Spectroscopy

A schematic of the SXAPS spectrometer is shown in Figure 3. In SXAPS, the total soft X-ray intensity emitted by a sample under electron bombardment is measured as a function of incident electron energy. Electrons from a tungsten filament (F) impinge on the sample (S) to be studied. The collector electrode (E) and the stainless-steel chamber wall to the right of the grid (G) constitute an X-ray detector (D). The grid, which is negatively biased with respect to the filament, offers no effective obstruction to the X-rays emitted, while electrically screening the X-ray detector assembly from the filament-target assembly. The entire system is maintained under ultrahigh vacuum conditions. X-rays passing through the grid strike the walls of the chamber, which act as a photocathode. The resulting photoelectrons are collected by a positively biased collector electrode. The extraction of the signal is accomplished by a potential modulation technique. A reference signal (R) is superimposed on the target and the resulting variations in photocurrent are synchronously detected in the first differential mode with a phase-lock amplifier. The appearance potential spectrum represents the detection output versus the accelerating potential. It is generally advantageous to make AEAPS measurements in the second-derivative mode because the secondary electron emission does not exhibit a linear dependence on incident electron energy.

The resolution of the spectrometer depends on several factors, such as the voltage drop across the filament, the thermal energy spread of the incident

**Figure 3** The soft X-ray appearance potential spectrometer. S, sample; F, filament; E, collector electrode; D, X-ray detector; G, grid; R, reference signal; L, induction coil; C, condenser.

electrons, and the amplitude of the modulation voltage. Taking such factors into consideration, the resolution in APS can be kept below 0.5 eV.

## Experimental Spectra

Unoccupied states of the insulator MnO (100) have been investigated by core electron energy loss (CEELS) and SXAPS at the oxygen 1s and manganese 2p thresholds. The SXAPS at the oxygen 1s threshold is shown in Figure 4. The peaks B and C have been identified as transitions into unoccupied metal 4s and 4p bands, which hybridize with oxygen 2p bands. The peak D is also observed in the CEELS spectrum and is due to multiple scattering processes of electrons excited into continuum states at neighboring oxygen ions. No differences were observed between SXAPS and CEELS spectra indicating delocalized character of the states at the ligand. Therefore, the electron correlation can be neglected in the SXAPS spectrum at the oxygen 1s threshold.

The SXAPS spectrum at the manganese 2p threshold is shown in Figure 5. The first two peaks (peaks A

and B) are interpreted as excitations of manganese 2p electrons into empty metal 3d levels. Significant differences were observed between this spectrum and the corresponding CEELS spectrum. The peak C is not a one-electron process but an excitation with two electrons involved, because this peak is absent in the CEELS spectrum. The differences have been attributed to the different number of localized electrons involved in the respective excitation channels and to the influence of electron correlation in the SXAPS spectrum at the Mn 2p threshold. The energetic difference between peaks B and C in Figure 5 was observed to be  $\sim 10$  eV, which is nearly the value of the electron correlation energy  $U_{dd}$  calculated on the basis of a configuration-interaction cluster model.

The DAPS spectra of La and Ce have been compared with ionization loss spectroscopy (ILS) spectra under various oxygen exposures. These two spectroscopies may respond in different ways to the changing chemical environment if Coulomb correlation effects are not negligibly small. The DAPS and ILS spectra for lanthanum are shown in

**Figure 6** (A) 3d ILS of La at various oxygen exposures. Both line shapes and peak positions change slightly with increasing oxygen exposures. (B) 3d DAPS of La at various oxygen exposures. Compared with ILS, DAPS change more significantly in peak positions. (Reprinted with permission from Lu M, Quang-ji Z, and Hua Z (1995) Observations of Coulomb correlation effects during oxidation processes of La, Ce, Cr and Ti by ILS and DAPS. *Surface Science* 341: 182–189.)

**Figure 6.** In the case of lanthanides the 4f electrons are highly localized and are well correlated. The Fermi level,  $E_F$ , crosses the 5d6s valence band and the unoccupied 4f level is located above  $E_F$ . During the oxidation of La, the three hybridized (5d6s) valence electrons are transferred to the oxygen 2p derived level until the final oxide phase  $\text{La}_2\text{O}_3$  is formed. At this stage, the shapes of spectra of La and  $\text{La}_2\text{O}_3$  should be similar, a fact that has been experimentally confirmed. The DAPS peaks were observed to show greater changes in peak energies than the corresponding ILS peaks. Further analyses of the data showed that the difference between the peak positions in these two spectroscopies contained three items of Coulomb correlation energies:

$$\delta D = \delta U_{ii} + \delta \varepsilon_i + \delta U_{ic} \quad [6]$$

where  $D$  is the difference between peak positions in DAPS and ILS,  $U_{ii}$  is the Coulomb repulsion energy between the excited electron and the impinging

electron at level  $i$ ,  $\varepsilon_i$  is the unoccupied energy level  $i$  on which the excited electron resides, and  $U_{ic}$  is the Coulomb attraction between the excited electron at level  $i$  and the corresponding core hole created in the excitation process. The  $\delta$  indicates changes in the corresponding values. From the spectral analysis,  $\delta D$  was observed to be  $\sim 2.0$  eV between  $\text{La}_2\text{O}_3$  and La. With increasing oxidation of La, the increase in the  $\delta D$  values has been explained as due to the competition between the increase of the 4f energy level  $\varepsilon_f$  and the relatively less decrease of  $U_{fc}$  (the Coulomb attraction between the excited electron at  $E_F$  and the corresponding core hole created in the excitation process) until the  $\text{La}_2\text{O}_3$  layer is formed.

In case of cerium, the spectra showed indication of the 4f electrons taking part in bonding during the formation of  $\text{CeO}_2$ . After an exposure of 1020 Langmuir, a broadening of the spectra was observed and has been attributed to the overlapping of the  $\text{Ce}_2\text{O}_3$  and  $\text{CeO}_2$  spectra. The value of  $\delta D$  was found to increase with increasing oxygen exposure and was largely attributed to the increase in  $\varepsilon_f$ . Compared to  $\text{Ce}_2\text{O}_3$ , this  $\varepsilon_f$  for  $\text{CeO}_2$  showed a dramatic decrease and has been explained in terms of the localized f electron taking part in bonding (from  $\text{Ce}_2\text{O}_3$  to  $\text{CeO}_2$ ). As a result of this bonding the interaction between the excited electron and the electrons below  $E_F$  should be greatly reduced. This will then lead to a significant decrease in  $\varepsilon_f$ , as observed.

Chromium nitride thin films have received increasing attention in recent years due to their interesting physical properties, such as oxidation resistance, corrosion resistance, and wear behavior. The technique of AEAPS has been used to investigate the bonding characteristics in  $\text{CrN}_x$  thin films as a function of nitrogen content. The N/Cr atomic ratio as determined by AES is 0.2, 0.4, and 1.0. The structure has been determined by X-ray diffraction and was found to change from bcc + hexagonal to hexagonal to cubic with increasing nitrogen content. The  $\text{L}_{2,3}$  core level spectra of chromium in the films are shown in Figure 7. In this figure, sample 1 corresponds to the N/Cr atomic ratio of 0.2, sample 2 to 0.4, and sample 3 to 1.0. It is a plot of the second differential Auger electron yield as a function of the sample potential. The spectra have been normalized for equal intensity just below the threshold. In AEAPS, the inelastic event occurring leaves the incident and the core electrons in available states at  $E_F$ . Above this threshold, the electrons can lie in a range of vacant states that conserve energy. The strength of the signal at the threshold therefore represents the unoccupied DOS at  $E_F$ . From the Figure 8 it is seen that the signal strength increases in all of the CrN films compared with elemental chromium. This represents an

**Figure 7** Normalized chromium  $L_{2,3}$  level AEAPS spectra for the CrN films and elemental chromium. The emission current was 2 mA and the modulation voltage was 1 V<sub>p-p</sub>. The strength of the signal (i.e., the density of unoccupied states at the Fermi level) is more for the films. **Figure 8** Area under the Cr  $L_{2,3}$  levels in CrN films and elemental chromium. The minima were aligned and the areas under the peaks were evaluated in a fixed energy window after the background subtraction. The plot represents variation in the total unoccupied density of states in the films compared with elemental chromium. (Reproduced from Chourasia AR and Hood SJ (2001) Auger electron appearance potential spectroscopy. *Surface and Interface Analysis* 31: 291–296.)

increase in unoccupied DOS at  $E_F$  as a result of chemical bonding between Cr and N. The increase in the unoccupied states of chromium, therefore, represents a charge transfer from Cr to N in the CrN

films. The established direction of charge transfer is consistent with Pauling's electronegativity criterion. In the films, however, the signal strength is found to decrease with an increase in the nitrogen content. The unoccupied DOS, therefore, decreases as the concentration of nitrogen increases in the films. This shows a decrease in charge transfer from Cr to N in the films. These observations are consistent with XPS and XAS investigation performed on the CrN films.

In the case of metal–nonmetal refractory compounds, the bonds are formed in two ways: a  $\sigma$ -bond is formed by an overlap of nonmetal 2p with metal 3d- $e_g$  orbitals, and a  $\pi$ -bond is formed by an overlap of non-metal 2p with metal 3d- $t_{2g}$  orbitals. In the CrN<sub>x</sub> films increasing the N/Cr atomic ratio will increase the number of antibonding nitrogen p-states. This would lead to raising of the unoccupied Cr d-states resulting in a decrease in both the  $\sigma$ - and the  $\pi$ -bonds as the concentration of nitrogen increases. This is consistent with the conclusions on charge transfer in these films.

In electron spectroscopies the investigation of excitation and transport processes poses problems owing to the many possible electron interactions. Because of the threshold energies used in APS the inelastic interaction excludes the incident electron from the number of electrons that can contribute to the signal, unlike in other spectroscopies. Also, the processes connected with the excitation of a particular core level can be studied separately. Since DAPS involves no relaxation process, it is possible to investigate the excitation probability for particular sublevels.

Knowledge of information depth obtained from a surface analysis technique determines its wide use in surface analysis. Only a few attempts have so far been made to gather information depth based on APS; this is one of the reasons why APS has not become a popular technique for surface analysis. The information depth obtained from APS technique correlates well with that determined by AES.

## Density of States

The technique of APS reveals a localized DOS because the matrix element governing the core hole production involves the very short range wave function of the initial core electron states. APS reveals information regarding the total DOS of all symmetries in the conduction band. Also, APS does not require a dispersive analyzer. This accounts for the extreme simplicity of the APS spectrometer. APS provides information regarding the elemental identification, chemical bonding, density of unoccupied

states, nearest-neighbor configuration in the surface layer, and the mechanism of excitation and transport processes occurring in the surface region of the sample. Wide scope still exists for theoretical and experimental work in this field. When the different aspects of APS are fully exploited, this spectroscopy will become a popular technique for materials characterization of surfaces.

## Introduction

Although many techniques have been used to analyze solid surfaces, most of them provide information on the static behavior of surface properties. By desorbing the surface materials and adsorbates into vacuum and by observing these species, we can obtain the dynamic features of the surface reaction and temporarily existing intermediates as well as the static behavior of the surface properties.

As in the case of other surface analytic methods, in order to examine well-defined surfaces, the sample surface must be prepared by cleaning and subsequent treatments such as adsorption and/or annealing processes in an ultrahigh vacuum (UHV). After that, the surface species must be desorbed from the surface by a specific excitation method and are analyzed by a specific detector. To induce desorption of the adsorbed species or the surface atoms, the surface is thermally excited by increasing the temperature (as in most cases) or electronically excited by irradiation

with electrons or photons. Although desorption can be induced by other methods such as energetic particle bombardment and application of electric fields, these are merely adapted to analyze surface properties. As a detector, a mass spectrometer is usually used. From the mass and the amount of desorbed species as a function of the experimental parameters, one obtains information on the surface properties and dynamic and temporal features of surface reactions. Optical methods are also used to selectively detect desorbed species.

In this article, the commonly used thermal desorption technique is first discussed in detail. Then other related methods are introduced briefly. Surface analyses based on electronic transition-induced desorption that provide unique information on the surface structure are presented.

## Thermal Desorption

By raising the surface temperature, adsorbates, trapped or bound on the surface, and surface atoms can be desorbed, even though they only exist on the surface during the surface reaction. Weakly bound surface species desorb early when the surface

states, nearest-neighbor configuration in the surface layer, and the mechanism of excitation and transport processes occurring in the surface region of the sample. Wide scope still exists for theoretical and experimental work in this field. When the different aspects of APS are fully exploited, this spectroscopy will become a popular technique for materials characterization of surfaces.

## Introduction

Although many techniques have been used to analyze solid surfaces, most of them provide information on the static behavior of surface properties. By desorbing the surface materials and adsorbates into vacuum and by observing these species, we can obtain the dynamic features of the surface reaction and temporarily existing intermediates as well as the static behavior of the surface properties.

As in the case of other surface analytic methods, in order to examine well-defined surfaces, the sample surface must be prepared by cleaning and subsequent treatments such as adsorption and/or annealing processes in an ultrahigh vacuum (UHV). After that, the surface species must be desorbed from the surface by a specific excitation method and are analyzed by a specific detector. To induce desorption of the adsorbed species or the surface atoms, the surface is thermally excited by increasing the temperature (as in most cases) or electronically excited by irradiation

with electrons or photons. Although desorption can be induced by other methods such as energetic particle bombardment and application of electric fields, these are merely adapted to analyze surface properties. As a detector, a mass spectrometer is usually used. From the mass and the amount of desorbed species as a function of the experimental parameters, one obtains information on the surface properties and dynamic and temporal features of surface reactions. Optical methods are also used to selectively detect desorbed species.

In this article, the commonly used thermal desorption technique is first discussed in detail. Then other related methods are introduced briefly. Surface analyses based on electronic transition-induced desorption that provide unique information on the surface structure are presented.

## Thermal Desorption

By raising the surface temperature, adsorbates, trapped or bound on the surface, and surface atoms can be desorbed, even though they only exist on the surface during the surface reaction. Weakly bound surface species desorb early when the surface

temperature is gradually increased. Thus, the amount of the desorbed species as a function of temperature shows the order of the weakness of the adsorption. This technique is called thermal desorption spectroscopy, temperature programmed desorption (TPD), or occasionally flash desorption. The temperature of desorption depends on the surface species, the adsorption site, and the surface properties as well as the speed of the temperature rise. Since desorption occasionally occurs through a surface reaction, the desorption temperature also depends on the detailed surface reaction. Thus, through the thermal desorption technique, one obtains a wide variety of information on the surface, such as the surface species, the number of them, the adsorption site, the surface structure, the binding energy of the adsorbates, and the interadsorbate interaction.

## Experimental Technique for Thermal Desorption

Thermal desorption can be performed with a rather simple UHV setup, consisting of a heater for raising the temperature of the sample surface, a detector for sensing the desorption species, and a gas doser for preparing the sample surface. A mass spectrometer is usually used as a detector and is helpful in identifying the desorbed species based on their mass spectrum. A multiplexer is often used to detect several species simultaneously (strictly speaking, sequentially with repeated quick scans) with a single temperature rise. It is necessary to minimize the temperature rise of the materials contained in the UHV system other than the specimen.

The concentration of adsorbates and surface atoms to be analyzed is limited to  $\sim 10^{15} \text{ cm}^{-2}$  for a single monolayer. Although the detection sensitivity of the desorbed species may be enhanced by using an integral method where the pumping speed is reduced and the desorbed species are accumulated, this method is no longer adopted at present because unknown factors due to the wall of the vacuum chamber hamper the interpretation of the results. Nowadays, one directly detects the species as they are ejected from the sample surface by using a system with a sufficiently high pumping speed. In this case, the detection sensitivity is crucially important. To detect species with high sensitivity, the ionizer of the mass spectrometer is placed just in front of the sample. In order to suppress the background signal, the ionizer is sometimes covered with a shield case with an aperture in the line of sight of the sample surface, which is optionally differentially pumped. The shield case is made of an inert material such as quartz, on which

**Figure 1** A typical setup for desorption measurements.

species are not adsorbed. To avoid detecting species desorbed from wall surfaces other than the sample, the shield case is sometimes cooled using liquid nitrogen as shown in **Figure 1**. Furthermore, a quick rise in the temperature improves the sensitivity. The heat capacity of the materials around the sample should be reduced. For a quantitative discussion, the temperature ramp rate needs to be carefully controlled, therefore a temperature controller with a temperature sensor and a feedback loop is occasionally adopted. Furthermore, a quick response is required for time-resolved measurements, which will be discussed later. In this case, the local pumping speed around the sample and the spectrometer should be made high enough by equipping them with a cryopanel or an open structure. In order to supply chemicals to the sample surface, a gas doser is used. A single capillary or multicapillary is sometimes used to restrict the gas-exposed area just around the sample surface and to align the direction and control the exposure distribution.

## Interpretation of Thermal Desorption Results

To extract quantitative information, mathematical considerations are necessary. Most simply, the peak position and the shape of the temperature programmed desorption spectrum are analyzed on the basis of the method proposed by Redhead. Here a sufficiently high pumping speed is assumed. Since the detected signal is proportional to the amount of the desorbed species under the experimental conditions, the desorption rate during a temperature rise is given

by the Polanyi–Wigner formula:

$$N(t) = -\frac{d\theta}{dt} = v_n \theta^n \exp\left(-\frac{E}{kT}\right) \quad [1]$$

where  $E$ ,  $n$ ,  $\theta$ , and  $v_n$  are the activation energy of desorption (binding energy of adsorption species), the order of desorption, the surface coverage, and the rate constant, respectively. For monomolecular and bimolecular desorptions,  $n$  is, respectively, 0 and 1.

Mostly a linear temperature rise,  $T = T_0 + \beta t$  is used, where  $\beta$  is the ramp rate of the temperature.  $E$ ,  $n$ , and  $v_n$  are assumed to be constant as a function of surface coverage, which may be valid only in the case of the low-coverage regime. The desorption rate being an exponential function of  $-E/kT$ , it increases with temperature. Since the desorption rate is proportional to the surface coverage of adsorbates as well, it decreases after reaching a low coverage. Thus, a desorption spectrum shows a peak. For the peak position ( $T_p$ ) of the TPD spectrum for  $n$  of 1 and 2, the following expressions hold:

$$E/kT_p^2 = (v_1/\beta) \exp(-E/kT_p) \quad (n = 1) \quad [2]$$

$$E/kT_p^2 = (v_2\theta_0/\beta) \exp(-E/kT_p) \quad (n = 2) \quad [3]$$

where  $\theta_0$  is the initial coverage of adsorbates. The activation energy is a key for discussing the reaction pathway. For analysis, it is derived from the peak position under an assumed rate constant of  $v = 10^{13} \text{ s}^{-1}$ . It should be noted that the peak temperature varies with the ramp rate of the temperature. Using a set of measurements from different ramping rates, the rate constant and the activation energy can be derived simultaneously.

For the first-order desorption, the peak position is independent of the initial coverage, and for desorption of the second or higher orders, it shifts toward a lower temperature with increasing coverage. Thus, from the peak positions for different coverages, we can obtain the reaction order. The peak shape of the TPD spectrum is also an interesting feature. While the peak is asymmetric for the first-order desorption, it is, in an ideal case, symmetric for second-order desorption as shown in Figure 2.

When the coverage is high, the activation energy and other parameters depend on the coverage, e.g., as a result of interadsorbate interactions and changes in atomic arrangement. Quantitative analyses for the desorption parameters that take into account coverage have been described on the basis of desorption rate isotherms, expressing the desorption rate as a function of the coverage for a constant temperature. The surface coverage during the TPD measurement

**Figure 2** Schematic shapes of TPD spectra for first- and second-order desorptions.

**Figure 3** Schematic illustration of the method of estimating the adsorbate coverage during TPD measurement from integration of the TPD spectrum.

(Figure 3) can be derived from the TPD spectrum obtained, using

$$\theta = A \int_T^\infty N dT \quad [4]$$

where  $A$  is the unit conversion constant. For such analysis, a set of TPD spectra obtained at different initial coverages are used. The example in Figure 4 shows a set of spectra. From these spectra, the desorption rate for a given coverage and temperature is derived and is called the desorption rate isotherm. For a given coverage, the logarithm of the desorption rate as a function of  $1/T$  can be plotted (Arrhenius plot). The slope of this plot gives the activation energy for a given coverage without assuming the desorption rate (the preexponential factor in the

**Figure 4** Set of TPD spectra for various initial coverages; CO desorbed from a CO-adsorbed Rh(100) surface. The ramp rate is  $5 \text{ K s}^{-1}$ . (Reproduced with permission from van Bavel AP, Hops-taken MJP, Curulla D, *et al.* (2003) Quantification of lateral repulsion between co-adsorbed CO and N on Rh (100) using temperature-programmed desorption, low-energy electron diffraction, and Monte-Carlo simulations. *Journal of Chemical Physics* 119: 524–532; © American Institute of Physics.)

equation). From a set of TPD spectra for various temperature ramp rates one also obtains the desorption rate isotherm. Other methods such as threshold TPD have been proposed.

## Other Methods Related to Thermal Desorption

The surface reaction generally proceeds through multiple complex pathways. These pathways are unraveled by using the temperature-programmed technique. Under the experimental conditions of TPD, the reaction products and other surface species are desorbed from the sample surface by increasing the surface temperature after a sufficient amount of chemical species is adsorbed at a low temperature. This method is called the temperature programmed reaction method. Furthermore, we can observe the desorbed species during their exposure to the source

**Figure 5** Results of SKS measurements; the signal intensities of desorbed species from an Ni(111) surface under irradiation of  $\text{CD}_3\text{OH}$  as a function of the temperature. (Reproduced with permission from Gates SM, Russell JN Jr., and Yates JT Jr. (1985) Scanning kinetic spectroscopy (SKS): A new method for investigation of surface reaction processes. *Surface Science* 159: 233–255; © Elsevier.)

species. This method is called scanning kinetic spectroscopy (SKS). **Figure 5** shows examples of scanning kinetic spectra. In this method, the desorbed species are observed using a collimated quadrupole mass spectrometer when the temperature is raised at a constant ramp rate under molecular beam irradiation with a controlled flux.

The desorption feature provides information on the reaction taking place at the surface. The velocity and angular distributions of desorbed species are measured by using a special setup with a rotating chopper with slits for a time-of-flight (TOF) measurement and a rotatable detector. A pseudorandom chopper is often used to perform time-resolved measurements efficiently that reflect the dynamical behavior of the surface reaction. The mechanism can be discussed on the basis of the detailed balance of desorption and adsorption. In the case of the absence of an activation barrier for adsorption, desorption shows the behavior for thermal equilibrium

conditions, i.e., an angular distribution under the cosine law and a Maxwellian velocity distribution at the surface temperature. On the other hand, when there is an activation barrier for adsorption, these distributions are different. Since the desorbed molecules are accelerated by the potential barrier for adsorption, the angular distribution is centered to the surface-normal and the velocity distribution is shifted to the higher-velocity side. The detailed behavior can be discussed in the framework of the multidimensional potential energy surface. As for the desorption resulting from surface reactions, the desorbed species are sometimes hyperthermally excited, showing specific velocity and angular distributions. It has been demonstrated that 'hot atoms' are generated during a surface reaction. In the case of misoriented surfaces, another feature is observed due to the anisotropy of the surface. In order to observe the vibrational and rotational states of the desorbed species, which are strongly related to the reaction mechanism, optical methods such as laser-induced fluorescence and resonance-enhanced multiphoton ionization are used to detect directly the electronically, vibrationally, and rotationally excited states of the desorbed species.

In order to obtain information on the dynamic behavior of the surface reaction, the modulated beam method is sometimes used. In this method, the desorbed species are detected using a time-resolved method, while the sample surface is irradiated with molecular beams that are temporarily modulated using a chopper or pulsed molecular beams. In the past, the distortion of the beam shape due to the scattering (adsorption/desorption) from the surface was mainly observed using, for example, a lock-in detection method where the dynamical feature of the reaction is described in terms of the phase shift. Recently the TOF technique has been used in combination with pulsed molecular beams and a multichannel scaler to obtain results that reflect the dynamical behavior of the inelastic surface scattering. If the molecules are trapped in a precursor state at the surface and energy equilibrium is attained, the velocity distribution should be the Maxwellian of the surface temperature; otherwise, it should be narrower than the Maxwellian, partially retaining the velocity distribution of the incident beams. It should be noted that the observed TOF spectrum is a convolution of the velocity distributions of the incident and scattered beams (Figure 6). From the TOF spectrum, one obtains the degree of energy exchange during scattering, which is important in discussion of the surface reaction in detail, especially for the direct reaction. In the case where the surface residence time is long compared with the time resolution of the

**Figure 6** TOF spectra of Ar scattered from the H-terminated W(100) surface for pulsed Ar beams with incident energies of 0.085 and 0.18 eV. measurement, we can directly measure the residence time. In this case, the residence time is derived from deconvolution of the spectrum containing the surface residence time, as shown in Figure 7. Since the

precursor state does not have a barrier for adsorption, the Arrhenius plot of the inverse of the surface residence time provides the activation barrier as mentioned in the discussion of TPD.

## Desorption Induced by Electronic Excitation

The surface species are also desorbed as ions or neutrals through electronic excitation induced by the irradiation of electrons or photons with energies from 10 eV to more than 1000 eV. This is called desorption induced by electronic transition (DIET). Photon-stimulated desorption shows a clear selection rule, and the results are easy to interpret. However, the number of photon energies available in the laboratory is limited. On the other hand, electron energies can be varied easily. Thus, electron-stimulated desorption is more widely used. By measuring the desorption rate through electronic excitations, one obtains information on the atomic geometry at the surface as well as the adsorbed species and the desorption mechanisms.

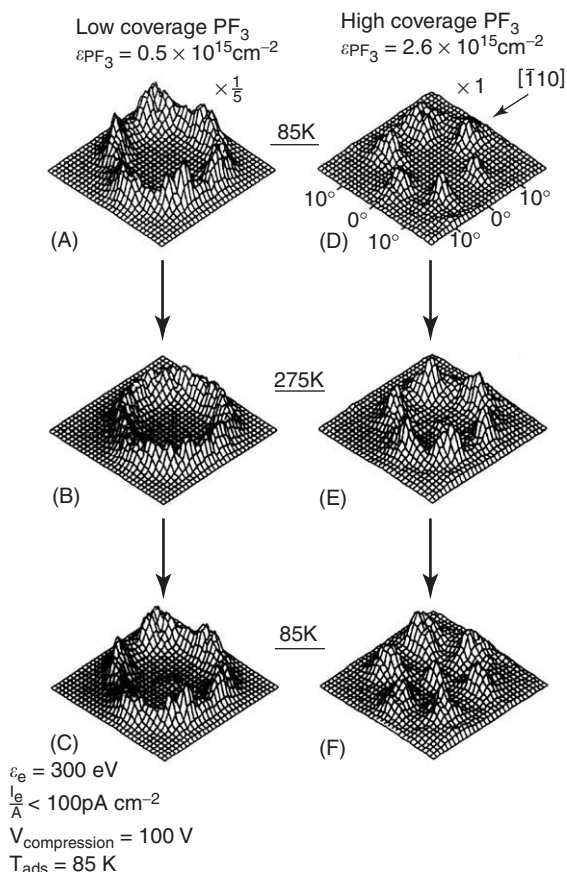

The mechanism of DIET was first discussed on the basis of the Franck–Condon principle. In this framework, the surface is electrically excited to a number of states, keeping the atomic location unchanged. In case of excitation to the repulsive part of the potential, ions or neutrals are released and desorbed when being accelerated by the repulsive potential as shown in Figure 8. This mechanism is called the Menzel–Gomer–Redhead mechanism. As for excitation by the impact of incident photons or electrons with

higher energies, inner shell electrons can be also excited. In this case, the electrons in a bonding state drop into the vacant inner shell, removing the same bonding state electron with a kinetic energy to conserve energy (Auger process). The surface species that are charged by losing a bonding electron are desorbed along the repulsive potential. This mechanism is called the Feibelman–Knotek model. In this mechanism, positive ions can be desorbed even from ionic crystals. The desorbing ions may be attracted from the surface by the image force. Occasionally, these species are neutralized and desorbed again if their lifetime is long enough.

The threshold energy or excitation function, as well as the velocity distribution of desorbed species, is a reflection of the desorption mechanism. From this information, the mechanism can be discussed. However, it should be taken into account that the

**Figure 8** Schematic illustration of the potential energy during DIETs.

**Figure 9** Typical result of ESDIAD for F ions desorbed from a  $\text{PF}_3$  preadsorbed Ni(111) surface with different initial coverages. The result at low coverage demonstrates that the  $\text{PF}_3$  rotates at a higher temperature. (Reproduced with permission from Yates JT, Alvey MD, Dresser MJ, Lanzillotto A-M, and Uram KJ (1988) Observation of molecular rotors on surfaces by ESDIAD: Studies of  $\text{PF}_3$  and  $\text{NH}_3$  chemisorption on Ni surfaces. In: *Desorption Induced by Electronic Transitions DIET III*, pp.100–108. Berlin: Springer-Verlag.)

spectra obtained are often broadened or shifted with respect to that for the gas-phase reaction due to the surface effect.

In the case of electronic excitation, the transition occurs in accord with the Franck–Condon principle. Here, the surface species are suddenly exposed to the repulsion potential, maintained at the same location as that just before excitation. In this case, the species are desorbed to the direction opposite to the broken bond. By using a setup with a spherical grid mesh generating a radial electric field and a fluorescent screen with a microchannel plate, one obtains 2D images corresponding to the atomic arrangement (Figure 9). This method is called electron-stimulated desorption ion angular distribution (ESDIAD). By using this method, it has been demonstrated that an adsorbate with a fixed orientation to the substrate in a low-temperature regime starts to rotate in a high-temperature regime.

The surface species can be desorbed also by a strong electric field of the order of  $10^{10} \text{ V m}^{-1}$ . It is well known that the electric field is then enhanced at the apex of the protrusion. This method is used in field ion microscopy.

## Introduction

Ion scattering is concerned with accelerating ions, causing them to impinge on a sample as a well-collimated beam, and analyzing the angle and energy distributions of the scattered ions. Ion scattering distinguishes itself by being a relatively simple technique, which can be applied for the analysis of both surface composition and surface structure. The technique was developed in the late 1960s and has since then matured to become an important research and analysis tool in many laboratories.

Traditionally, there has been a distinction between two different energy regimes for ion scattering as applied to surface analysis. At high ion energies (larger than  $\geq 100 \text{ keV}$ ), the analysis is normally carried out with protons or helium ions, the scattering process is determined by the Rutherford cross-section, and the scattered particles suffer little neutralization along the exit path. Depending upon the exact application, the techniques are termed Rutherford backscattering spectrometry (RBS), high-energy ion scattering (HEIS), or medium-energy ion scattering (MEIS). On the other hand, low-energy ion scattering (LEIS) or ion-scattering spectroscopy (ISS), as the technique is also known, is based on scattering of either inert-gas ions (He or Ne) or alkali ions (Li, Na, or K) with energies of the

order of 1 keV. At this energy, there are strong screening effects on the Coulomb potential, and a significant, frequently path-dependent neutralization of the scattered particles is observed.

As will be evident from the following, there are two major differences between the two energy regimes. Quantitative measurements of composition are easier in the high-energy regime than in the low-energy regime. Also, in structural analysis HEIS and MEIS determine the position of surface atoms relative to the bulk-atom positions, while LEIS (ISS) measurements reveal relative positions between surface atoms.

## Theory

### Surface-Composition Analysis

Ion-scattering techniques are well suited for a quantitative analysis of the surface composition because the energy spectrum of scattered particles shows mass dispersion, and the scattering process has a well-defined cross-section at high energies. The two main techniques applicable in the high-energy regime are RBS and nuclear reaction analysis (NRA). RBS is most commonly used in cases where the atomic mass of a surface impurity or an adsorbate is larger than that of the substrate. Concentrations of light elements may be determined with NRA.

**High-energy regime** RBS is the subject of a separate chapter of this encyclopedia. Here, a short description of RBS is presented, with the emphasis on applications for surface analysis in the monolayer regime.

The energy  $E_1$  of the scattered particle is proportional to the incident energy  $E_0$ :

$$E_1 = KE_0 \quad [1]$$

where  $K$ , the kinematic factor, is given by

$$K = \left( \frac{(M_2^2 - M_1^2 \sin^2 \theta)^{1/2} + M_1 \cos \theta}{M_1 + M_2} \right)^2 \quad [2]$$

$M_1$  and  $M_2$  are the atomic masses of the incident ions and the target atoms, respectively, and  $\theta$  is the scattering angle in the laboratory system. This property is illustrated in **Figure 1**, which shows a  $^4\text{He}^+$  backscattering spectrum from a Si crystal covered with very thin layers of Cr and Au. Ions backscattered from the Si surface appear at  $\approx 1200$  keV. The continuum at lower energies is due to ions backscattered from Si after penetration into the crystal, leading to an energy loss. The two peaks corresponding to backscattering from Cr and from Au are clearly resolved and appear at energies determined by eqns [1] and [2]. The masses

**Figure 1** Rutherford backscattering spectrum ( $E_0 = 2$  MeV,  $\theta_{\text{LAB}} = 140^\circ$ ) from an Si crystal with thin layers of Cr ( $3 \times 10^{15}$  atoms  $\text{cm}^{-2}$ ) and Au ( $8 \times 10^{14}$  atoms  $\text{cm}^{-2}$ ) evaporated onto the surface. The continuum at low energies is due to ions backscattered from Si after penetration into the bulk. The energy of such ions can be related to the scattering depth.

of the surface constituents can therefore be identified with an energy-calibrated detection system. Unfortunately, the mass resolution is inherently poorer for heavy target atoms than for light ones.

For a quantitative analysis we consider the differential scattering cross-section in the laboratory reference frame, given by

$$\frac{d\sigma}{d\Omega} = \left( \frac{Z_1 Z_2 e^2}{2E} \right)^2 \frac{1}{\sin^4 \theta} \frac{\{[1 - ((M_1/M_2) \sin \theta)^2]^{1/2} + \cos \theta\}^2}{[1 - ((M_1/M_2) \sin \theta)^2]^{1/2}} \quad [3]$$

where  $Z_1$  and  $Z_2$  are the atomic numbers of the incident particle and target atom, respectively,  $E$  is the particle energy just before scattering, and  $e$  is the electron charge. Hence, the scattering yield  $Y$  from a given adsorbate of area density  $N_t$  (atoms  $\text{cm}^{-2}$ ) for a total number  $N_i$  of incident particles will be

$$Y = N_i N_t \left( \frac{d\sigma}{d\Omega} \right) \Delta\Omega \quad [4]$$

where  $\Delta\Omega$  is the solid angle of the detector system. Absolute densities of different elements present at the surface can therefore be determined.

Because of the small cross-sections, Rutherford backscattering is not well suited for an accurate determination of the abundance of light elements such as carbon and oxygen. Instead, NRA, sometimes called nuclear microanalysis, can be applied. The energy released in the reactions (the  $Q$  value) is quite high, resulting in high-energy reaction products that can be easily detected. In this case, the cross-sections

**Table 1** Nuclear reactions used for detection of light surface adsorbates

Element	Reaction
d( <sup>2</sup> H)	d( <sup>3</sup> He, p) $\alpha$
<sup>12</sup> C	<sup>12</sup> C(d, p) <sup>13</sup> C
<sup>14</sup> N	<sup>14</sup> N(d, p) <sup>15</sup> N
<sup>14</sup> N	<sup>14</sup> N(d, $\alpha$ ) <sup>12</sup> C
<sup>16</sup> O	<sup>16</sup> O(d, p) <sup>17</sup> O
<sup>16</sup> O	<sup>16</sup> O( <sup>3</sup> He, $\alpha$ ) <sup>15</sup> O
<sup>16</sup> O	<sup>16</sup> O( <sup>3</sup> He, p) <sup>18</sup> F
<sup>18</sup> O	<sup>18</sup> O(p, $\alpha$ ) <sup>15</sup> N

have no simple energy dependence. Table 1 lists some of the reactions used in surface analysis.

**Low-energy regime** Here, quantitative surface-composition analysis is less straightforward. The energy spectrum of scattered ions immediately gives a qualitative impression of the surface constituents, but it is difficult to convert the observed yields to absolute coverages for the following reasons: (1) the scattering cross-sections are less well known due to the strong screening of the Coulomb potential; (2) in most experimental systems only scattered ions are detected; and (3) shadowing effects may be important. The probability that an incident ion reaches the analyzer without neutralization depends on several parameters such as ion type, scattering depth, and the detailed trajectory. Some of the difficulties can be overcome by the choice of specific ions, application of time-of-flight (TOF) techniques, comparison to calibration samples, etc., but quantitative analysis is, in general, not straightforward in the low-energy regime.

However, LEIS (ISS) offers one advantage: an extreme surface sensitivity can be obtained with He ions because ions scattered at subsurface atoms will neutralize at the exit path. If only scattered ions are detected, the signal will therefore originate exclusively from the surface monolayer of atoms. This property is extremely useful in, for example, studies of surface segregation.

### Surface-Structure Analysis

Suppose that a beam of well-collimated, high-energy ions is incident on a crystalline substrate along a major crystallographic axis as illustrated schematically in Figure 2. Ions incident at the lowest impact parameters (the impact parameter is the distance at which the incident ion would pass the atom if no deflection took place) will undergo large deflections and scatter out of the crystal, while those at large impact parameters suffer small deflections and determine the flux of ions into the crystal. As a

**Figure 2** Formation of a shadow cone (S) behind a surface atom for beam incidence along a (vertical) row of atoms. The radius of the shadow cone at the second atom is denoted R. Additional deflections at the second atom have been neglected in the figure. As shown schematically, scattered ions are blocked in certain directions giving rise to a blocking cone (B).

consequence, a so-called shadow cone is formed behind the first atom, i.e., a region in space where, in a static representation, the incident flux is zero. The width of the shadow cone depends on the atomic numbers of the projectile and target atoms, and it increases with decreasing energy.

**High-energy regime** In the high-energy regime, a typical shadow-cone radius measured at the position of the second atom is  $\approx 0.1$  Å. For most materials, the one-dimensional, root-mean-square (rms) vibration amplitude of the atoms at room temperature is also  $\sim 0.1$  Å. The backscattering probabilities from the atoms behind the surface atom must therefore be taken into account. They may be calculated by a convolution of the flux distribution with the position distribution of the atoms. In general, such convolutions cannot be carried out on an analytical basis, and the calculation of backscattering probabilities is therefore based on Monte-Carlo-type computer simulations of a large number of ion trajectories.

Instead of calculating only actual backscattering events (which are very rare because of the small cross-sections), the backscattering probabilities for the atoms along the row are determined. Assuming that the row of atoms coincides with the  $z$ -axis, the normalized probability can be shown to take the following form:

$$P = \frac{\cos \psi}{2\pi\sigma^2 NdN_i} \sum_{i=1}^{N_i} \exp\left(-\frac{x_i^2 + y_i^2}{2\sigma^2}\right) \quad [5]$$

where  $\psi$  is the angle of incidence with the atomic row,  $\sigma$  the one-dimensional rms vibration amplitude,  $d$  the interatomic distance along the row,  $N$  the atomic density in the crystal,  $N_i$  the number of ion trajectories, and  $(x_i, y_i)$  determines the impact parameter.

While the outermost atoms are fully exposed to the incoming beam, the backscattering probability becomes negligible a few atomic distances into the crystal due to the shadowing effect. This strong reduction in scattering yield is illustrated in Figure 3, which shows a backscattering spectrum obtained on a W crystal for ion-beam incidence along a  $\langle 100 \rangle$  direction. The high-energy end of the spectrum exhibits a peak that corresponds to backscattering from the surface atoms. As shown in the applications section, information about the surface structure can be derived from an analysis of the energy and/or angular dependence of this surface peak. This is the basis of HEIS for surface structure analysis.

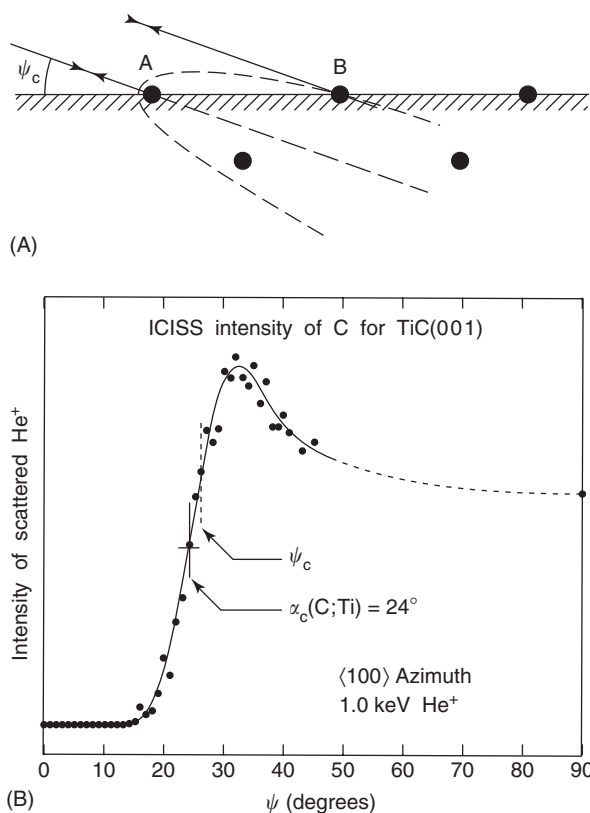

If backscattering takes place from a subsurface atom, this atom will act as a point source emitting particles, and the outgoing ions will be blocked in certain directions where a blocking cone is formed by a process similar to shadow-cone formation. This effect is also illustrated in Figure 2. To investigate the surface crystallography with MEIS, the angular distribution of the backscattered flux of particles is measured with the incident beam aligned to a major crystallographic axis. By a relatively simple extension, the calculation scheme outlined above may be used for the case of double alignment (shadowing and blocking) as well. Structural parameters are derived by optimizing the fit between the measured

**Figure 3** Backscattering spectrum for incidence of a 500 keV  $\text{He}^+$  ion beam along a  $\langle 100 \rangle$  direction of a W crystal. A surface peak, corresponding to backscattering from the surface layers, appears in the high-energy end of the spectrum.

angular distribution of scattered ions ('blocking spectrum') and calculated distributions for model structures.

**Low-energy regime** In the low-energy regime, quite similar directional effects are observed; however, due to the much lower energy, the shadow cones are considerably wider. This is exploited in a special version of LEIS, called impact collision ion scattering spectroscopy (ICISS) where a scattering angle close to  $180^\circ$  is used (in practice  $\geq 160^\circ$ ). In this mode, backscattered ions have experienced head-on collisions with the target atoms, and relative positions of surface atoms can be determined in the following manner (see Figure 4): If the angle of incidence  $\psi$  (measured relative to the surface plane) is below a critical value  $\psi_c$ , a surface atom B will be in the shadow cone from its nearest neighbor A, and consequently, no backscattering from the surface is

**Figure 4** Basic principle of ICISS. (A) For beam incidence at an angle  $\psi_c$  the edge of the shadow cone from atom A coincides with the position of atom B. (B) Experimental ICISS spectrum showing the scattering intensity from C in the TiC(001) surface as a function of angle of incidence  $\psi$ . The critical angle  $\psi_c$  is indicated. (Part B is reproduced with permission from Aono M and Souda R (1985) Quantitative surface atomic structure analysis. *Japanese Journal of Applied Physics* 24: 1249; © Institute of Pure and Applied Physics, Tokyo, Japan.)

possible. When  $\psi$  is increased, a sudden onset of backscattering intensity is observed around  $\psi_c$ , at which angle the edge of the shadow cone from atom A coincides with the position of atom B. If the detailed shape of the shadow cone is known (from theory or from measurements on known structures), the relative positions of atoms A and B can be determined, as will be discussed in the Applications section. Positions of subsurface atoms relative to surface atoms may be determined as well, although the analysis becomes less straightforward due to multiple deflections of the ions.

## Instrumentation

A detailed description of the experimental systems used for ion-beam crystallography cannot be included in the present article. Basically, an ultra-high-vacuum (UHV) system is coupled to a high- or low-energy ion accelerator via a differentially pumped beam line. There are two features that set the ion-scattering systems apart from most other UHV setups. One is a goniometer (high-precision manipulator), which allows the necessary, precise orientation of the crystalline sample relative to the incident ion beam over a large angular range. The other is some kind of detection system that provides an energy dispersion of the scattered ions.

In the high-energy regime, bakeable, implanted Si detectors are very convenient for this purpose and they have been used extensively in HEIS. They detect both neutral and charged scattered particles but have typical energy resolutions of 5 keV for protons and 15 keV for He particles, corresponding to a depth resolution  $\delta x > 10$  nm. Therefore, energy analysis of the backscattered particles with solid-state detectors does not provide a distinction between, for example, adsorption at surface and subsurface sites. Much better depth (and mass) resolution can be achieved with magnetic or electrostatic analyzers where energy resolutions of  $\Delta E/E \approx 3 \times 10^{-3}$  are typical. For MEIS toroidally shaped electrostatic analyzers are available, which, when equipped with a position sensitive detector, permit detection of ions in a large interval of scattering angles, thereby allowing a full angular distribution to be recorded at a fixed analyzer setting. To limit the size of the electrostatic analyzer, MEIS is typically performed at energies  $\sim 100$  keV. Energy resolutions below  $10^{-3}$  have been achieved, which in conjunction with special scattering geometries has led to monolayer depth resolution!

In the low-energy regime, electrostatic analyzers are most commonly used for energy analysis, but TOF

systems are also widespread. Such systems can detect both ions and neutrals, resulting in an increased sensitivity. However, for He scattering, where particles that are scattered beneath the surface layer are very effectively neutralized in the exit path, a loss of surface sensitivity is incurred in TOF systems.

## Applications

### Surface-Structure Analysis: Relaxation and Reconstruction

The termination of a solid by a surface modifies the atomic surroundings in terms of the atomic coordination and the distribution of conduction electrons. It is then to be expected that the equilibrium positions of the surface atoms will change in order to minimize the surface free energy. If the entire surface layer is shifted collectively inward or outward, the surface is said to be relaxed (contracted or expanded). If the atomic arrangement within the surface plane changes, the surface is said to be reconstructed. Both relaxation and reconstruction phenomena can be analyzed by ion scattering.

**Relaxation** Many structural problems can be addressed experimentally in both the high- and the low-energy regimes. As an example, consider surface relaxation. The application of the shadowing and blocking technique in MEIS to measure relaxations is illustrated in **Figure 5**, which shows (in a schematic way) the atomic configuration in a plane perpendicular to a face centered cubic (fcc) (001) surface that is assumed to be relaxed (contracted) by  $\Delta d_{12}$ . The ion beam is made incident along a crystal axis, and the scattered beam intensity is measured in an angular interval around an exit direction that coincides with a bulk axis. Any relaxation of the surface will result in an angular shift  $\Delta\alpha$  of the surface blocking cone away from the direction of the bulk axis, as observed in the recorded blocking spectrum.

**Figure 5** Basic principles for analysis of surface relaxation based on double alignment (shadowing and blocking). A relaxation will give rise to an angular shift between the blocking directions for bulk and for surface scattering.

This technique relies to a high extent on simple geometry in the basic analysis in the sense that the angular shift of the surface blocking dip is relatively insensitive to the magnitude of the surface vibrations, which, however, influence the shape and depth of the dip. However, to derive the exact geometry a detailed comparison between the experimental blocking spectrum and data calculated for various model structures (including multilayer relaxations) must be carried out for the scattering data in the full angular interval.

A special type of relaxation is observed on some compound surfaces where the two kinds of constituent atoms have opposite (inward and outward) displacements, resulting in a so-called 'rumpling' relaxation. This type of relaxation can be analyzed with low-energy ions using ICISS, as illustrated in **Figure 4B**, which shows some results from a study of the TiC(001) surface using 1 keV He<sup>+</sup> ions. The intensity of He<sup>+</sup> scattered from C atoms is shown as a function of angle of incidence measured from the surface, and the onset of scattering intensity is well defined although somewhat smeared out because of the thermal vibrations. It can be shown that the angle corresponding to roughly 80% of the maximum intensity is a better estimate of  $\psi_c$  than the angle corresponding to half-maximum intensity. Based on this rule,  $\psi_c$  is estimated to be  $\sim 26^\circ$ . Using the fact that the shape of the shadow cone from Ti (atom A in **Figure 4A**) is known from other measurements, the height of the C atoms (atom B) can then be determined relative to Ti. The result indicates that the rumpling of the TiC(001) surface is negligible ( $\leq 0.01$  nm).

**Reconstruction** The simple observations made in the section 'Theory: Surface structure analysis' can be used to determine the nature of phase transitions involving surface reconstruction. The W(100) surface and its interaction with hydrogen will serve as an example. Below a critical temperature  $T_c$  of  $\approx 210$  K, the clean W(100) surface is known to exhibit a  $(\sqrt{2} \times \sqrt{2})R45$  LEED pattern that corresponds to a reconstructed surface in which the surface atoms have significant lateral displacements. By saturating the surface with hydrogen or by heating the crystal above  $T_c$ , the LEED pattern changes to a  $(1 \times 1)$  pattern. The question is then whether this  $(1 \times 1)$  pattern corresponds to a truncated bulk surface. Lateral displacements of surface atoms will expose underlying atoms to the ion beam at normal incidence and hence increase the effective number of atoms per row, visible to the ion beam, above that expected for a truncated bulk surface. Some results from an ion-scattering study of the different phases

**Figure 6** Experimental surface-peak yields for normal incidence on W(100) as a function of temperature, measured with 1 MeV He ions. Open circles are for the clean surface, solid circles for the hydrogen exposed surface. The solid line is a computer simulation for an unreconstructed surface. The dashed line corresponds to a case in which all surface atoms have a lateral displacement component of 0.15 Å.  $T_c$  is the critical temperature for the phase transition. (Reproduced with permission from Stensgaard I, Purcell KG, and King D (1989) Evidence for a temperature induced order-disorder phase transition on W(100). *Physical Review B* 39: 897; © American Physical Society.)

are shown in **Figure 6**. The surface-peak yield was measured at normal incidence for the surface in the clean and the hydrogen-exposed states. It is evident that the data points for the clean surface (open circles) lie well above the calculated yield for the truncated bulk surface (solid line) and that the data points do not drop to this level above  $T_c$ . In fact, there is no discontinuity in yield across the transition-temperature region. This indicates that the surface atoms have similar lateral displacements in the high-temperature and the low-temperature phases that are therefore both reconstructed. The detailed nature of the phase transition (for example, whether it is a genuine order-disorder transition) and the structure of the high-temperature phase are topics beyond the scope of this article, but clearly the very simple measurements described above represent some important constraints on possible models.

**Figure 6** also displays a series of surface peak measurements (solid circles) as a function of temperature for a hydrogen exposure, which, if the hydrogen atoms stick to the surface, is sufficiently large to saturate the surface. The adsorption of hydrogen below  $\approx 320$  K obviously causes the surface to become unreconstructed, i.e., that the  $(\sqrt{2} \times \sqrt{2})R45$  low-temperature reconstructed phase converts into a truncated bulk structure. Above  $\approx 350$  K, it is not possible to saturate the W(100) surface with hydrogen.

How large are the lateral displacements of the surface atoms in the reconstructed phases? Some information on this problem can be deduced from a measurement of the number of visible surface atoms (surface peak yield) as a function of energy. The shadow-cone radius scales roughly inversely with the square root of the ion energy. For a given transverse displacement, the shadow cone is sufficiently wide at low energy to shadow the underlying atom, which, in turn, becomes fully exposed at high energies. In practice, the thermal vibrations tend to smear out the transition from the fully shadowed to the fully exposed state but the lateral displacements can still be deduced by comparison to simulated surface yields.

### Chemisorption Positions

A detailed knowledge of the positions of chemisorbed atoms is a necessary prerequisite for an understanding of most surface properties. The chemisorption positions can be derived from ion scattering in both the high- and the low-energy regimes.

In general, pure shadowing is not very well suited for determination of adsorption positions with high-energy ions. The adsorbates may shadow the substrate-surface atoms in a certain direction of incidence (cf. Epitaxy, below), but unless this direction coincides with a major crystal axis, the shadowing effect is small. Also, the thermal vibrations will reduce the shadowing.

Shadowing and blocking using MEIS can be applied if the adsorbate gives rise to a significant blocking dip, i.e., if the atomic number is not very small and the thermal vibrations are not too large. A full surface-structure analysis must then be undertaken to incorporate a possible adsorption-induced relaxation.

In the low-energy case, the analysis may proceed much along the same lines as described above for an ICISS analysis of the TiC(001) surface (the C atoms could be thought of as being chemisorbed on a Ti surface) although a more thorough analysis, of course, involves a complete scan of the incident angle as well as angular scans along different azimuthal directions.

### Epitaxy

The epitaxial growth of one material onto another (heteroepitaxy) is extremely important, especially in the field of semiconductors. The quality of relatively thick films can be investigated by the ion-channeling process, but ion scattering has also provided several examples of very basic studies of the initial stages of heteroepitaxy.

A classical example is the study of the initial growth of Au on Ag(111). Gold and silver form a

lattice-matched system, both being face centered cubic materials and having lattice parameters differing by only 0.2%. **Figure 7** shows room-temperature backscattering spectra from the clean Ag surface and for increasing thicknesses of the deposited Au layer. Note how the Ag surface peak diminishes as an Au surface peak appears. This indicates directly that the Au atoms give rise to a perfect shadowing of the Ag surface atoms and hence that the Au overlayers are registered with respect to the substrate, i.e., that the growth is epitaxial.

Epitaxial growth systems may be divided into different classes, according to the detailed growth mode: monolayer-by-monolayer growth (Frank-van der Merwe), pure three-dimensional islanding (Volmer-Weber) or three-dimensional islanding after completion of one or a few monolayers (Stranski-Krastanov). In the Au on Ag(111) case, the growth mode was revealed by monitoring the Au-Au shadowing effect. The ratio of the Au signal in the aligned to the nonaligned direction exhibited a pronounced decrease only after a total coverage of one monolayer had been reached, and the detailed shape of the curve was found to be consistent with the Frank-van der Merwe growth mode (layer by layer). Note that the total Au coverage is obtained by RBS.

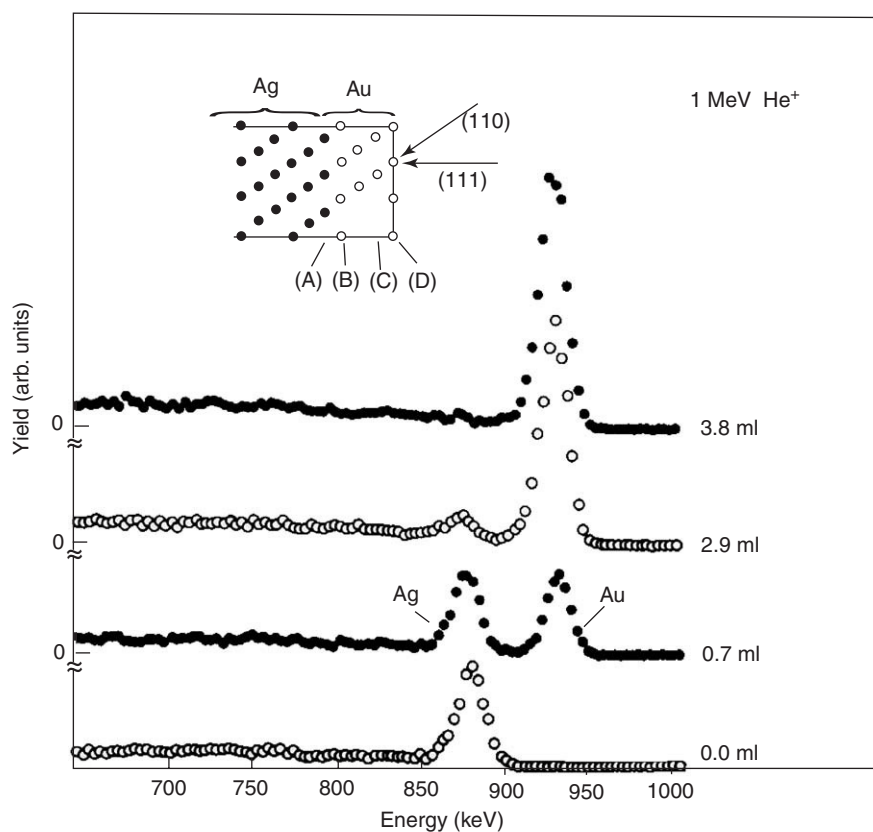

The almost perfect lattice match between Au and Ag is, of course, uncommon. For lattice mismatched systems the initial growth may again be pseudomorphic, but after completion of a critical number of layers, the strain energy built up in the thin film is relieved through the onset of misfit dislocations which destroy the shadowing.

Heteroepitaxial growth leads to buried interfaces with very important structural properties that determine, e.g., the Schottky barrier heights in the case of metal-semiconductor junctions. With the improved depth resolutions of the detection systems, structural studies by ion scattering of such interfaces are becoming increasingly feasible.

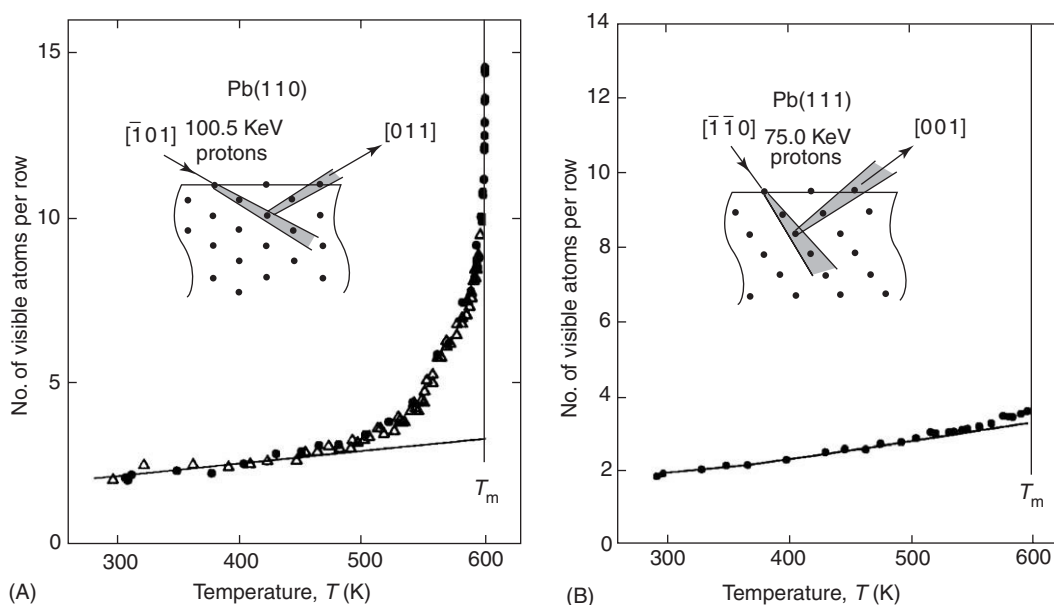

### Surface Dynamics and Melting

Based on numerous ion scattering studies of surfaces, a general picture has emerged (although exceptions have been reported): surface atoms have larger vibration amplitudes than bulk atoms, and the thermal displacement distributions for surface atoms are anisotropic, in general in such a way that rms amplitudes are larger for out-of-plane displacements than for in-plane displacements. Little is known about displacement correlations in the surface region.

As the temperature of a crystal is increased, the anharmonicity of the interatomic potentials gives rise to thermal expansion of the lattice and more

**Figure 7** Rutherford backscattering spectra from a Ag(111) crystal for ion incidence along a  $\langle 110 \rangle$  direction. The four spectra are for increasing coverages of Au (bottom to top). (Reproduced with permission from Culbertsen RJ, Feldman LC, Silverman PL, and Boehm H (1981) Epitaxy of Au on Ag (111) studied with high-energy ions scattering. *Physical Review Letters* 47: 657; © American Physical Society.)

**Figure 8** (A) Surface backscattering yields from Pb(110) as a function of temperature. The bulk melting temperature  $T_m$  is indicated. (B) As for (A) but for the Pb(111) surface. (Reprinted with permission from van der Veen JF and Frenken JWM (1991) *Surface Science* 251/252: 1; © Elsevier.)

pronounced anharmonic vibrational distributions. Some surfaces will exhibit roughening characterized by a proliferation of surface steps generated at a roughening temperature at which the free energy for creation of an atomic step becomes zero. Finally, when the thermal excursions of the atoms exceed a critical value, the crystal will begin to melt. As mentioned above, the atoms in the surface layer(s) show greater thermal excursions than the bulk atoms. This suggests that the surface layer may melt at a lower temperature than the bulk, and it may subsequently act as a nucleation center for further layer-by-layer melting, thus precluding superheating.

Direct observations of a reversible melting transition on crystalline surfaces can be observed with ion scattering. Using a shadowing/blocking geometry, the number of 'visible' surface layers of a Pb(110) crystal has been measured as a function of temperature. As shown in **Figure 8A**, the backscattering yield first increases slowly with temperature due to the expected increase in vibration amplitude. From  $\sim 470$  to  $\sim 560$  K, an additional increase is observed, which must reflect a positional disordering of the atoms in the surface region ('premelting'). As the temperature is further increased, the thickness of the quasiliquid layer diverges, following growth laws that can be predicted on the basis of thermodynamic theories of surface melting.

Not all surfaces exhibit surface melting; it appears to depend on the specific free energy  $\Delta\gamma$  that the dry solid surface has in excess of a solid surface wetted by its own liquid. For positive values of  $\Delta\gamma$ , the surface lowers its free energy by melting; for negative values, it stays dry. The condition for surface melting is more readily fulfilled for open surfaces such as fcc(110) than for close-packed ones. In accordance

with this, no surface melting was observed on Pb(111) (cf. **Figure 8B**).

So far, only a limited number of surfaces have been investigated for surface melting, but this is certainly a field where ion-scattering experiments have made a very substantial contribution.

### Introduction

Nuclear reaction analysis (NRA) and elastic recoil detection (ERD) are part of the suite of ion beam analysis (IBA) techniques. They are commonly used for the elemental depth profiling of materials in a wide range of fields, e.g., from biological and medical to the semiconductor industry.

IBA techniques, which also include Rutherford backscattering spectrometry (RBS) and particle induced X-ray emission (PIXE), require the use of a particle accelerator to produce a beam of mono-energetic MeV ions which is then incident on a target. The ions may interact with atomic electrons within the target to produce characteristic X-rays or they may collide with nuclei. If an ion collides with a nucleus it may scatter, cause the nucleus to be ejected (recoiled) or undergo a nuclear reaction resulting in the emission of particles and/or  $\gamma$ -rays. NRA involves the detection of particles or  $\gamma$ -rays caused by nuclear reactions in the target while ERD involves the

pronounced anharmonic vibrational distributions. Some surfaces will exhibit roughening characterized by a proliferation of surface steps generated at a roughening temperature at which the free energy for creation of an atomic step becomes zero. Finally, when the thermal excursions of the atoms exceed a critical value, the crystal will begin to melt. As mentioned above, the atoms in the surface layer(s) show greater thermal excursions than the bulk atoms. This suggests that the surface layer may melt at a lower temperature than the bulk, and it may subsequently act as a nucleation center for further layer-by-layer melting, thus precluding superheating.

Direct observations of a reversible melting transition on crystalline surfaces can be observed with ion scattering. Using a shadowing/blocking geometry, the number of 'visible' surface layers of a Pb(110) crystal has been measured as a function of temperature. As shown in **Figure 8A**, the backscattering yield first increases slowly with temperature due to the expected increase in vibration amplitude. From  $\sim 470$  to  $\sim 560$  K, an additional increase is observed, which must reflect a positional disordering of the atoms in the surface region ('premelting'). As the temperature is further increased, the thickness of the quasiliquid layer diverges, following growth laws that can be predicted on the basis of thermodynamic theories of surface melting.

Not all surfaces exhibit surface melting; it appears to depend on the specific free energy  $\Delta\gamma$  that the dry solid surface has in excess of a solid surface wetted by its own liquid. For positive values of  $\Delta\gamma$ , the surface lowers its free energy by melting; for negative values, it stays dry. The condition for surface melting is more readily fulfilled for open surfaces such as fcc(110) than for close-packed ones. In accordance

with this, no surface melting was observed on Pb(111) (cf. **Figure 8B**).

So far, only a limited number of surfaces have been investigated for surface melting, but this is certainly a field where ion-scattering experiments have made a very substantial contribution.

## Nuclear Reaction Analysis and Elastic Recoil Detection

**R W Smith**, Centre d'Etudes Nucléaires de Bordeaux Gradignan (CENBG), Gradignan, France

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Nuclear reaction analysis (NRA) and elastic recoil detection (ERD) are part of the suite of ion beam analysis (IBA) techniques. They are commonly used for the elemental depth profiling of materials in a wide range of fields, e.g., from biological and medical to the semiconductor industry.

IBA techniques, which also include Rutherford backscattering spectrometry (RBS) and particle induced X-ray emission (PIXE), require the use of a particle accelerator to produce a beam of mono-energetic MeV ions which is then incident on a target. The ions may interact with atomic electrons within the target to produce characteristic X-rays or they may collide with nuclei. If an ion collides with a nucleus it may scatter, cause the nucleus to be ejected (recoiled) or undergo a nuclear reaction resulting in the emission of particles and/or  $\gamma$ -rays. NRA involves the detection of particles or  $\gamma$ -rays caused by nuclear reactions in the target while ERD involves the

detection of nuclei recoiled by the incident beam. RBS involves detecting the back scattered ions and PIXE involves detecting the characteristic X-rays.

One of the many advantages of IBA techniques is their nondestructive nature. All the techniques have their own strengths and weaknesses. To use NRA, knowledge of the sample's composition is required to determine which reactions to use. Although it generally has a better sensitivity and resolution than ERD, in most cases it can only profile one element at a time. This is also a benefit in the sense that unwanted signals from other components of the target do not interfere. ERD has the advantage of being very easy to use and unlike RBS can detect hydrogen. ERD is generally used for the easy profiling of light elements in a heavy matrix while RBS is more suited to depth profiling heavy elements in a light matrix. PIXE is a useful multielemental technique for determining a sample's composition but cannot be used to depth profile elements in the same way as NRA, ERD, and RBS.

The technique to use depends on a number of factors including the information required and the equipment available. In their simplest form, NRA (nonresonant), ERD, and RBS can all be carried out using the same equipment.

## Theory/Principles

### Nuclear Reaction Analysis

A typical nuclear reaction caused by an ion incident on a target may be written as

Figure 1 NRA geometry.

cross-section while resonant NRA utilizes reactions that have narrow resonances in the cross-section.

**Nonresonant NRA** In the basic reaction, conservation of total energy gives

$$m_X c^2 + E_X + m_a c^2 + E_a = m_Y c^2 + E_Y + m_b c^2 + E_b \quad [1]$$

where  $E_X$ ,  $E_a$ ,  $E_Y$ , and  $E_b$  are the kinetic energies and  $m_X$ ,  $m_a$ ,  $m_Y$ , and  $m_b$  are the rest masses of the particles. The  $Q$  value, the energy released during the reaction, is written as

$$Q = (m_X + m_a - m_Y - m_b)c^2 \quad [2]$$

If the  $Q$  value is positive the reaction is said to be exothermic and if the  $Q$  value is negative the reaction is said to be endothermic. By use of conservation of energy and linear momentum, an equation for  $E_b$  dependent on the incident ion energy  $E_a$  and detector angle  $\theta$  can be derived:

$$E_b^{1/2} = \frac{(m_a m_b E_a)^{1/2} \cos \theta + \{m_a m_b E_a \cos^2 \theta + (m_Y + m_b)[m_Y Q + (m_Y - m_a)E_a]\}^{1/2}}{m_Y + m_b} \quad [3]$$

where  $a$  is the energetic ion,  $X$  is the target, and  $C^*$  is the compound nucleus from which the reaction products  $Y$  and  $b$  (particle or  $\gamma$ -ray) are emitted. The geometry for this type of reaction is shown in Figure 1. Usually  $b$  is detected and its properties used for analysis. A more compact way of expressing the same reaction is  $X(a,b)Y$ ; the compound nucleus is not included because it is an intermediate state.

The probability of a reaction taking place is governed by its cross-section  $\sigma$  and is normally measured experimentally for a given incident particle energy and detector angle  $\theta$ . Nonresonant NRA uses reactions that have a smooth slowly changing

An equation for  $E_Y$  can be derived in the same way.

As the incident ions traverse the sample they lose energy primarily due to collisions with atomic electrons. This causes the energy of the products from nuclear reactions to change, hence producing a range of energies corresponding to different depths. By measuring the energies of these products (typically at backward angles) and taking account of the energy lost by both the incident ion on entering the target and the reaction product on leaving the target, the depth of interaction can be determined and hence an elemental depth profile produced. In some cases a particle filter is used to reduce the background in the detector and should be accounted for in the energy loss calculations.

The yield of a nuclear reaction from an element of thickness  $t$  at depth  $d$  can be calculated, providing that the cross-section changes slowly with energy and that the energy loss is small over the thickness, from the following:

$$\text{Yield}_b = \frac{Q_C \Omega (d\sigma/d\Omega)(\theta, E_a) N_{AV} t \rho}{Q_a \cos((\pi/2) - \phi) A} \quad [4]$$

where  $\text{Yield}_b$  is the number of counts (particles) resulting from a reaction with the element at depth  $d$  (cm) (normal to the surface) in the target,  $Q_C$  is the collected charge (C),  $Q_a$  is the charge on the ion a (C),  $\Omega$  is the solid angle (sr) subtended by the detector at the target,  $(d\sigma/d\Omega)(\theta, E_a)$  is the differential cross-section at angle  $\theta$  ( $\text{cm}^2 \text{sr}^{-1}$ ) for the incident ion's energy  $E_a$  at depth  $d$ ,  $N_{AV}$  is Avogadro's constant ( $6.023 \times 10^{23} \text{ mol}^{-1}$ ),  $t$  is the thickness at depth  $d$  in the target (cm),  $\rho$  is the density of the element at depth  $d$  in the target ( $\text{g cm}^{-3}$ ),  $\phi$  is the angle of incidence (rad) to the target and  $A$  is the atomic weight of the element (g).  $N_{AV} t \rho / A$  (areal density) is sometimes replaced with  $Nt$  where  $N$  is the number of atoms per cubic centimeter.

By measuring the number of counts originating from an element at depth  $d$  in the target for a set time, the concentration (areal density) of the element at that depth can be calculated using the above equation. If the energy loss is not small or if the cross-section changes quickly with energy, the single layer should be split into multiple layers for which the above equation can be used.

The depth resolution can be improved by reducing the incident beam energy (i.e., increasing the stopping power) or tilting of the sample. When using either method, changes in the cross-section should be taken into account. Both these methods have the disadvantage of decreasing the profiled depth.

**Resonant NRA** This uses a reaction that has one or more narrow resonances in the cross-section. Due to the energy loss of the ions traversing the sample, the depth at which resonance occurs can be changed by altering the incident beam energy. By scanning the energy of the beam and detecting the reaction products (normally  $\gamma$ -rays), the depth profile of a particular element can be produced. The concentration (areal density) and depth can be calculated in a similar way with modifications to that for nonresonant NRA. For the best depth resolution, the narrowest resonance should be chosen but the energy and cross-section of the resonance should also be taken into consideration.

## Elastic Recoil Detection

Ions incident on a target may collide with an atom of lower mass causing it to recoil in the forward direction. This recoiling atom, which is detected and used for analysis, has an energy  $E_2$  as follows:

$$E_2 = K \times E_0$$

where

$$K = \frac{4M_1 M_2 \cos^2 \theta}{(M_1 + M_2)^2}$$

known as the kinematic factor,  $M_1$  and  $M_2$  are the mass of the incident and recoiled particles,  $\theta$  is the angle of scatter and  $E_0$  is the energy of the incident particle as shown in **Figure 2**. This technique is sometimes known as forward recoil spectrometry (FRoS).

Recoiled atoms of different mass from the surface therefore have different energies and measuring these energies at a particular scattering angle enables their identification. Also, as the incident ions traverse the sample they lose energy causing the energy of the resultant recoils to be less than those from the surface. The depth profile and concentration (areal density) can be calculated in a similar way to that for nonresonant NRA. For the concentration calculation the differential cross-section is replaced by the differential recoil cross-section – Rutherford or non-Rutherford – which can be calculated. A particle filter is normally placed in front of the detector to prevent scattered incident ions and unwanted recoils from entering it. When analyzing the data the energy lost by recoils in this filter must be taken into account.

The standard setup for many materials (e.g., polymer films) usually uses a 3 MeV  $^4\text{He}$  beam incident on the sample at a glancing angle (to improve the resolution) but there are a few variations.

**Low-energy ERD (LE-ERD)** The use of low-energy ions reduces the thickness of the particle filter required and increases the stopping efficiency of the beam. This results in an improved depth resolution but limits the depth that can be profiled.

**Figure 2** ERD geometry.

**Heavy-ion ERD (HI-ERD)** The use of heavy ions such as  $^{12}\text{C}$  increases the stopping efficiency of the beam, minimizing the thickness of particle filter required. This results in an improvement in depth resolution but limits the depth that can be profiled. The possibility of beam damage must also be considered. The heavy-ion accelerators required for this technique are not as widely available as those used for standard ERD.

**Transmission ERD** Transmission ERD uses a different geometry to standard ERD and requires the sample to be thinner than the range of the recoiled atoms. The beam is usually incident on the sample at or near normal incidence and recoils are detected using a detector placed directly behind it. It has the advantage of an improved sensitivity but the profiled depth is very limited.

**Time-of-flight ERD (TOF-ERD)** In ERD there is a built-in mass–depth ambiguity which can complicate the analysis of the results. This ambiguity is present because the energy of the recoiled atoms depends on both the mass of the target atom and the depth of interaction. This ambiguity can be avoided by using TOF-ERD. The geometry of the sample is the same as for standard ERD but before the particle is detected it passes through a TOF detector (two thin timing foils) that enables determination of its velocity. The velocity of ions with the same energy but different masses will be different. This results in measurements of both the energy and mass of the recoiled atoms. This setup does not require a particle filter because it can discriminate between recoils and

scattered ions. This improves the depth resolution but the equipment required is expensive and complicated.

## Instrumentation/Experimental Apparatus

The equipment required to perform NRA and ERD is very similar. A particle accelerator (e.g., Van de Graaff or Tandem Van de Graaff) is used to produce a beam of monoenergetic MeV ions, which is then directed down a beam line and into a target chamber, all of which are under vacuum. There are many different experimental setups in use. **Figure 3** shows the main components of both a simple millibeam line and a microbeam line. The millibeam line is typically used for nonresonant NRA and ERD and produces a beam of diameter of order millimeters. The microbeam line shown here has been used for a position scanned microbeam NRA technique and produces a beam of diameter of order micrometers. The resonant NRA technique would use a similar setup to those shown here but with the addition of equipment to scan the energy of the beam.

After the accelerator, a set of X–Y deflection plates direct the beam into a momentum selecting magnet which selects ions of a particular energy and species and directs them down the desired beam line. The energy feedback slits are linked to the accelerator and help to ensure that the beam energy is kept constant.

In the millibeam line, the ions may then pass through an optional circular aperture of a few millimeters after which they are guided into the target

**Figure 3** The basic components of a simple NRA and ERD setup.

chamber by a set of X–Y deflection plates. Before the chamber there is a pair of vertical slits which may be used to reduce the beam width if necessary. Inside the chamber the sample stage can be rotated.

In the microbeam line, X–Y deflection plates are used to guide the ions through a circular aperture of size ranging from 25  $\mu\text{m}$  to 1 mm that also acts as the object for a magnetic quadrupole lens system. They then pass through a set of computer controlled X–Y raster scanner deflection plates that enable them to be scanned over an area of the sample a few square millimeters. Finally the magnetic quadrupole lens focuses the collimated beam by a factor of five in both the  $x$  and  $y$  directions onto the surface of the sample. Inside the chamber the sample stage can be moved in the  $x$  direction to allow other samples to be positioned in the beam.

The chambers are isolated from each beam line using a gate valve. Particles are detected at backward or forward scattering angles using silicon surface barrier detectors inside the chambers.  $\gamma$ -Rays can be detected using a scintillation detector (such as sodium iodide activated with thallium – NaI(Tl) or bismuth germanate –  $\text{Bi}_4\text{Ge}_3\text{O}_{12}$  usually referred to as BGO) or an intrinsic germanium detector which is normally located outside the chamber. The detectors are connected to acquisition electronics and computer software, which for the microbeam line enable particles or  $\gamma$ -rays detected to be correlated with the position of the scanning beam. The samples can also be cooled in the chambers using an isolated liquid  $\text{N}_2$  cold finger, the use of which is discussed in the applications section. The charge incident on the sample can be measured by using a Faraday cup before the sample or by measuring the current through the sample using a current integrator.

An external beam can be produced by passing the ions (focused if necessary) through a small thin window into air. With one of these setups, instead of using deflection plates, the beam can be scanned over a large surface of the sample by moving the sample itself.

## Applications

Tables 1 and 2 show some of the recently used non-resonant and resonant nuclear reactions, respectively. In general these reactions are used to depth profile the element of interest but can also be used to determine the concentration of a particular element in a sample. The following sections describe some of the many applications of NRA and ERD.

### Hydrogen Analysis

Hydrogen is probably the most common elemental contaminant, the presence of which can seriously

affect the electrical, mechanical, and chemical properties of some materials. Other than resonant NRA and ERD, there are very few techniques available to measure hydrogen contamination. This has led to their common/widespread use making hydrogen analysis one of their more important applications. The depth profiling of hydrogen is generally carried out using the resonant nuclear reaction  ${}^1\text{H}({}^{15}\text{N},\alpha\gamma){}^{12}\text{C}$  with the 6.385 MeV resonance which for most applications offers the best depth resolution and sensitivity. Depth resolutions of  $\sim 5$  nm in thin polymer films with the beam at an angle of  $12^\circ$  to the sample have been achieved but the resolution quickly degrades with depth. Profiling depths of up to several micrometers are possible. The  ${}^1\text{H}({}^{19}\text{F},\alpha\gamma){}^{16}\text{O}$  and  ${}^1\text{H}({}^7\text{Li},\gamma){}^8\text{Be}$  reactions have also been used with the advantages that a  ${}^{19}\text{F}$  beam is easier to produce and the  ${}^7\text{Li}$  reaction allows profiling to greater depths.

ERD can be easily used to profile hydrogen but generally has a poorer depth resolution ( $\sim 80$  nm with a profiling depth of  $\sim 0.8$   $\mu\text{m}$  for thin polymer films) than that obtained using resonant NRA.

However, it does have the advantage of being a very simple technique that does not require the complicated beam energy scanning equipment that is required for resonant NRA.

These techniques have been used to profile the hydrogen content of many materials, e.g., electronic materials, metals, superconductors, and polymers. They have also found use in water diffusion studies by profiling of the hydrogen component as discussed later.

### Depth Profiling Deuterium-Labeled Molecules

The  $D(^3\text{He},p)^4\text{He}$  nonresonant reaction has been used to study the diffusion of deuterium and deuterium-labeled molecules into a wide variety of materials.  $^3\text{He}$  ion beam energies of between 0.7 MeV, giving a resolution of 30 nm and a profiling depth of 0.1  $\mu\text{m}$  with the beam at a  $15^\circ$  angle to the sample, and 2 MeV giving a resolution of 400 nm and a profiling depth of 8  $\mu\text{m}$  with the beam normally incident, with the reaction products detected at an angle of  $165^\circ$  are usually used. These produce high-energy protons of  $\sim 12\text{--}14$  MeV which are well separated in the particle spectrum from the alpha particles of  $\sim 1\text{--}3$  MeV. Due to the kinematics of this reaction as the  $^3\text{He}$  ions lose energy by traversing the sample the

resultant protons and alpha particles emitted at backward angles increase in energy.

For several years this reaction was used to study interpolymer diffusion in thin films by deuterating the polymer of interest. **Figure 4** shows the particle spectrum resulting from a 0.7 MeV  $^3\text{He}$  ion beam incident on a test sample consisting of 32.3 nm DPS/63.3 nm PS/32.3 nm DPS (PS, polystyrene; DPS, deuterated polystyrene) at an angle of  $10^\circ$ . The high-energy proton and low-energy alpha particle peaks are from the DPS layers and the triple alpha peaks are from a radioactive source in the chamber used for calibration of the system. The second proton and alpha particle peaks are lower due to a decrease in the cross-section, i.e., the  $^3\text{He}$  beam energy has fallen below 0.7 MeV where the cross-section peaks.

ERD has also been used to depth profile deuterium in polymer thin films. It is able to profile both hydrogen and deuterium simultaneously but has a smaller profiled depth and poorer resolution when compared to the  $D(^3\text{He},p)^4\text{He}$  NRA technique.

To further increase the profiling depth of this technique the use of this reaction was combined with a position scanned  $^3\text{He}$  ion microbeam. The resulting technique has been used to study molecular ingress/diffusion into various materials by labeling the molecules of interest with deuterium. Water molecules are labeled by adding heavy water ( $\text{D}_2\text{O}$ ) and other

**Figure 4** Particle spectrum acquired from a DPS/PS/DPS sample with a 0.7 MeV  $^3\text{He}$  beam at an angle of  $10^\circ$ . A threshold level was applied to the acquisition electronics.

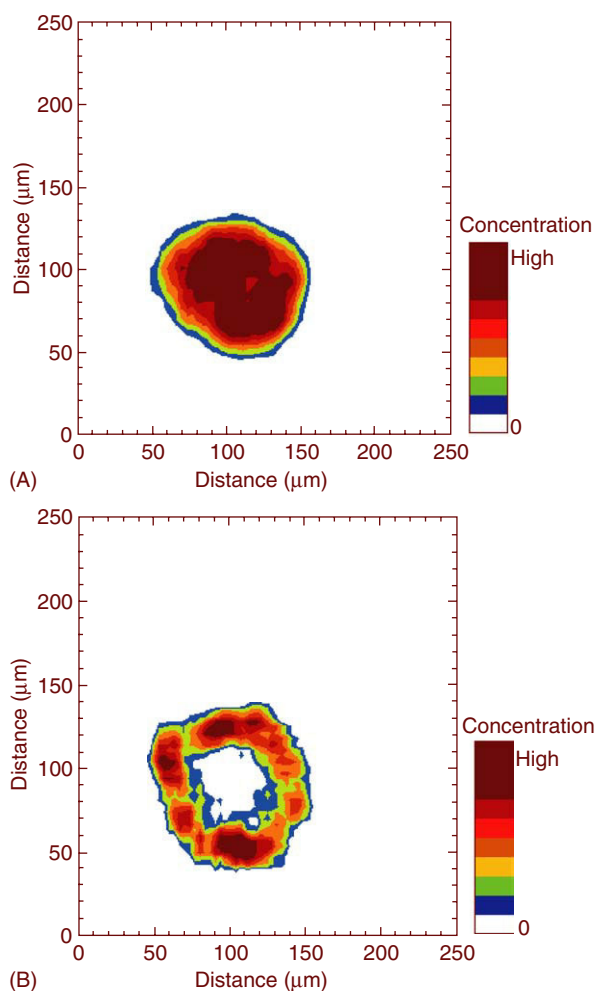

hydrogen containing molecules are labeled by deuteration. After the sample has been exposed to the deuterium-labeled molecules, it is cut to reveal a cross-section and then plunged into liquid nitrogen. This prevents the evaporation of the diffused molecules and fixes the diffusion profile. A  $^3\text{He}$  micro-beam is then raster scanned over the surface of the cross-section and the detected protons from the  $\text{D}(^3\text{He},\text{p})^4\text{He}$  reaction correlated with the position of the beam to produce a two-dimensional area map showing the location of the diffused molecules. During analysis, the sample is normally back-cooled with liquid nitrogen to prevent the molecules from being lost to the vacuum and also to reduce heating induced by the beam. If combined with PIXE, elements within the sample (e.g., sulfur present in hair or silicon present in glass) or the molecules themselves can also be located. The resolution depends on the size of the beam ( $\mu\text{m}$ ) and the distance between each dwell point, but the profiled depth is in principle only dependent on the ability to expose the sample to the beam. This technique has recently been used to study the diffusion of a deuterated hair dye into hair. For this hair dye to be effective and remain fast it was necessary for it to diffuse below the surface of the hair. **Figure 5A** shows a two-dimensional plot of detected sulfur X-rays showing the distribution of sulfur and hence the location of the hair. **Figure 5B** shows a two-dimensional plot of detected protons showing the distribution of deuterium and hence the location of the deuterated hair dye. It is clear from observation of these images that the hair dye has diffused well into the hair proving its effectiveness. Other applications have included the study of surfactants into hair, water diffusion into fiber optic pressure sensors, and water and drug diffusion in drug-release polymers.

### The Investigation of Nuclear Materials Using NRA

Minor actinides present in some nuclear waste produce large quantities of helium when they decay. When considering materials for storage of this waste, it is necessary to have some knowledge of helium diffusion in the material matrix. Helium diffusion into possible materials has been simulated by exposing them to a  $^3\text{He}$  ion beam (i.e., implantation). The implanted helium has then been profiled using the  $^3\text{He}(\text{D},\text{p})^4\text{He}$  nonresonant nuclear reaction enabling diffusion coefficients to be determined.

### Techniques to Study Water Diffusion

There are a few techniques that can be used to profile water ( $\text{H}_2\text{O}$ ) diffusion. The oxygen component can be profiled by labeling the water with  $^{18}\text{O}$  and using

**Figure 5** Two-dimensional plots showing the distribution of (A) sulfur and (B) deuterium in the hair. (Reprinted with permission from Smith RW and Clough AS (2002) Depth profiling of diffusion into cylindrical matrices using a scanning micro-beam. *Nuclear Instruments and Methods in Physics Research B* 188: 126–129; © Elsevier.)

the nonresonant  $^{18}\text{O}(\text{p},\alpha)^{15}\text{N}$  nuclear reaction to profile it. The hydrogen can be profiled using the  $^1\text{H}(^{15}\text{N},\gamma)^{12}\text{C}$  resonant nuclear reaction or ERD. If deuterium-labeled water ( $\text{D}_2\text{O}$ ) is used then its diffusion can be profiled using the  $\text{D}(^3\text{He},\text{p})^4\text{He}$  nuclear reaction techniques as described previously or ERD. The technique to use depends on the material being investigated, the depth to be profiled, and the ability to distinguish the water from the matrix. The hydrogen and oxygen nuclear reactions have both been used together to profile water diffusion into quartz. Using a combination of techniques in this way makes it possible to investigate the diffusion of the hydrogen and oxygen components separately and to study their effect on the diffusion mechanism.

### Analysis of Implanted Ions Using NRA

Ion implantation of materials, to change its properties, has many important applications in materials science and semiconductor technology. Several nonresonant and resonant nuclear reactions have been used for the profiling of such implantations. The 0.992 MeV resonance of the  $^{27}\text{Al}(p,\gamma)^{28}\text{Si}$  resonant nuclear reaction has, for example, been used to profile the thermal diffusion of aluminum in aluminum-implanted stainless steel when heated to temperatures of between 450°C and 650°C.

### NRA and ERD with External Beams (Including Simultaneous Analysis of Carbon, Nitrogen, and Oxygen)

The nondestructive nature of MeV IBA methods make them especially suitable in investigating fragile and precious objects. The use of PIXE with an external beam is a well-established technique that enables elemental analysis of large and/or delicate samples that could not be put in a vacuum chamber, e.g., art and archaeological objects. NRA (in conjunction with PIXE and RBS) has been used with an external deuteron beam for the simultaneous depth profiling of carbon, nitrogen, and oxygen in historical objects by using, among others, the  $^{12}\text{C}(d,p_0)^{13}\text{C}$ ,  $^{14}\text{N}(d,p_5)^{15}\text{N}$ , and  $^{16}\text{O}(d,p_1)^{17}\text{O}$  nuclear reactions. Preliminary experiments using ERD with an external  $^4\text{He}$  beam have been carried out to depth profile hydrogen and deuterium in precious stones. These have been relatively successful but there are some difficulties with the setup.

### Nonstandard ERD Techniques

LE-ERD and HI-ERD have both been used to profile deuterium in PS thin films with a better depth resolution than standard ERD but suffer a large decrease in profiling depth. LE-ERD has used a 1.3 MeV  $^4\text{He}$  beam with tilting of the sample to give a depth resolution of 14 nm and a profiling depth of 150 nm. HI-ERD has used a 2.4 MeV  $^{12}\text{C}$  beam with tilting of the sample to give a resolution of 8 nm and a profiling depth of 100 nm.  $^{20}\text{Ne}$  and  $^{40}\text{Ar}$  beams have also been used giving similar resolutions and profiling depths. HI-ERD can detect elements heavier than hydrogen and deuterium but radiation damage to the sample is a possibility.

### Developments in Data Analysis Programs

There have been several recent developments in the computer programs used to analyze NRA and ERD data.

The IBA DataFurnace utilizes the simulated annealing algorithm to analyze RBS, ERD, and

nonresonant NRA data in a fully automated way with minimum intervention. The user has to only input the data, the experimental conditions, and the elements present in the sample. No iterative procedure is involved although data can be simulated if required. Data from the same sample using different experimental conditions or techniques can be analyzed simultaneously and all the information taken into account to produce the final result.

SIMNRA is a program intended for the simulation of non-Rutherford backscattering, nonresonant NRA, and ERD data. The user is required to construct a layered target from which a simulation algorithm produces a simulated spectrum. The user then compares the simulation to the data and makes changes to the target description as necessary. In order to produce a target description the user must have some knowledge of the target composition. It does, however, have the option of fitting spectra using a least squares algorithm and parameters supplied by the user.

WinRNRA is a fitting program that converts resonant NRA yield curves into concentration depth profiles. It can be used to analyze data from a single element or isotope in an otherwise homogeneous target.

## Concluding Comments

NRA and ERD can be used to study elemental/molecular diffusion into a wide range of materials and can be used in conjunction with other complementary techniques such as PIXE and RBS. The sensitivity of the different techniques described here depends on a large number of factors including the experimental setup, detection efficiency, etc. but levels of about parts per thousand to parts per million have been reported. Excluding the position scanned microbeam NRA technique, depth resolutions ranging from several nanometers to several 100 nm for depths of up to several micrometers have been reported, with the resolution often degrading with depth.

There are a few potential future developments. The possibility of combining the position scanned  $^3\text{He}$  microbeam NRA technique and the  $\text{D}(^3\text{He},p)^4\text{He}$  nonresonant nuclear reaction technique to produce three-dimensional profiles has been discussed in the literature.

The size of focused ion beams has decreased in recent years so that it is now possible to produce beams of order 100 nm in size, i.e., nanobeams. The use of smaller beams with the position scanned microbeam NRA technique will improve the spatial resolution but will decrease the yield. For delicate samples where the current cannot be increased, this

may make it necessary to acquire data for longer and/or improve the particle detection efficiency.

When using an external beam there is also the possibility of producing large elemental maps of several centimeters over the sample surface by moving the sample itself over the beam.

Several new data analysis programs have been developed in recent years making the interpretation and analysis of data simpler and quicker. With modern computers it is also possible to analyze the data on-line, i.e., almost as soon as it has been acquired.

# Secondary Ion Mass Spectrometry of Polymers

D Briggs, Malvern, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Secondary ion mass spectrometry (SIMS), when carried out in the 'static' (i.e., zero damage) mode, is a uniquely powerful tool for the molecular characterization of polymer surfaces. Its molecular specificity also allows the detection and characterization of additives and contaminants, whose presence at the surface can cause major changes in surface behavior, at the submonolayer level. Modern instruments based on time-of-flight (ToF) mass analyzers and liquid-metal ion sources are capable of chemical imaging with a spatial resolution of well below 1  $\mu\text{m}$ .

## Physical Basis

In SIMS, the sample, in ultrahigh vacuum (UHV) ( $<10^{-7}$  Pa), is bombarded with energetic ions (typically 8–25 keV depending on the source, see below). These penetrate below the surface to a distance of

several nanometers whilst transferring their energy to the material. In the immediate vicinity of the primary ion track, where the energy density is highest, many bonds are broken and atoms are set in motion. Secondary and higher generation collisions set up a collision cascade radiating from the impact point. Isomerization of the original translational energy also leads to electronic and vibrational excitation. As a result of the collision cascade, fragments of the material close to the surface can be desorbed (sputtered) into the vacuum. These fragments range in size from single atoms to large assemblies. Most of the sputtered material is neutral but  $\sim 1\%$  is charged (positively or negatively). These secondary ions, the vast majority being singly charged, can be extracted into a mass spectrometer for mass analysis.

As with gas-phase organic mass spectrometry, SIMS spectra are information-rich and provide fingerprints. However, the processes leading to the spectra (both positive and negative ion spectra are utilized) are not well understood. The charged fragments can be formed directly in the collision cascade, or by ion/electron attachment, electron impact, and ion–molecule reactions in the selvedge (the affected region near the surface which may have

may make it necessary to acquire data for longer and/or improve the particle detection efficiency.

When using an external beam there is also the possibility of producing large elemental maps of several centimeters over the sample surface by moving the sample itself over the beam.

Several new data analysis programs have been developed in recent years making the interpretation and analysis of data simpler and quicker. With modern computers it is also possible to analyze the data on-line, i.e., almost as soon as it has been acquired.

# Secondary Ion Mass Spectrometry of Polymers

D Briggs, Malvern, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Secondary ion mass spectrometry (SIMS), when carried out in the 'static' (i.e., zero damage) mode, is a uniquely powerful tool for the molecular characterization of polymer surfaces. Its molecular specificity also allows the detection and characterization of additives and contaminants, whose presence at the surface can cause major changes in surface behavior, at the submonolayer level. Modern instruments based on time-of-flight (ToF) mass analyzers and liquid-metal ion sources are capable of chemical imaging with a spatial resolution of well below 1  $\mu\text{m}$ .

## Physical Basis

In SIMS, the sample, in ultrahigh vacuum (UHV) ( $<10^{-7}$  Pa), is bombarded with energetic ions (typically 8–25 keV depending on the source, see below). These penetrate below the surface to a distance of

several nanometers whilst transferring their energy to the material. In the immediate vicinity of the primary ion track, where the energy density is highest, many bonds are broken and atoms are set in motion. Secondary and higher generation collisions set up a collision cascade radiating from the impact point. Isomerization of the original translational energy also leads to electronic and vibrational excitation. As a result of the collision cascade, fragments of the material close to the surface can be desorbed (sputtered) into the vacuum. These fragments range in size from single atoms to large assemblies. Most of the sputtered material is neutral but  $\sim 1\%$  is charged (positively or negatively). These secondary ions, the vast majority being singly charged, can be extracted into a mass spectrometer for mass analysis.

As with gas-phase organic mass spectrometry, SIMS spectra are information-rich and provide fingerprints. However, the processes leading to the spectra (both positive and negative ion spectra are utilized) are not well understood. The charged fragments can be formed directly in the collision cascade, or by ion/electron attachment, electron impact, and ion–molecule reactions in the selvedge (the affected region near the surface which may have

**Figure 1** Relative intensities of diagnostic fragments from poly(methyl methacrylate) (+  $m/z$  126 and -  $m/z$  185) as a function of primary ion dose (using 8 keV  $\text{Cs}^+$ ). Individual spectra were acquired with a dose of  $<5 \times 10^{11}$  ions  $\text{cm}^{-2}$ . (Reproduced with permission from Briggs D and Fletcher IW (1997)  $\text{Cs}^+$  ion beam damage of poly(vinyl chloride) and poly(methyl methacrylate) studied by high mass resolution ToF-SIMS. *Surface and Interface Analysis* 25: 167–176; © John Wiley & Sons Ltd.)

some characteristics of a plasma), or by unimolecular decomposition of fragments with high internal energies in the vacuum.

For the study of organic materials, in particular, it is essential to limit the primary ion dose, so that the spectrum is representative of undamaged material (the 'static' SIMS regime). The aim is to ensure that no part of the surface receives more than one primary ion impact (affecting an area of order 10 nm diameter) during the analysis. By measuring spectra as a function of primary ion dose it is possible to determine the 'static SIMS limit', i.e., the dose above which the spectra are dose dependent. **Figure 1** illustrates such data for poly(methyl methacrylate), a representative polymer (the origins of the chosen fragments are described in section 'polymer spectra'). Under the conditions used the static SIMS limit is a primary ion dose of  $\sim 3 \times 10^{12}$  ions  $\text{cm}^{-2}$ .

There are few hard data that relate to the SIMS information depth for polymers, but the consensus view is that this is of the order of 1 nm. Atomic fragments may emerge from somewhat deeper below the surface but large molecular species arise only from the uppermost molecular layer or two.

## Instrumental Aspects

The early developments of static SIMS (largely driven by polymer surface analysis requirements in terms of practical application) were carried out with noble gas

ion sources and quadrupole mass analyzers (QMS). The latter had the benefits of compactness, ready availability, and relatively straightforward adaptability to the use of SIMS in UHV systems. Although all the essential features of polymer surface analysis were introduced using this technology, the QMS has major limitations for static SIMS. First, it is a serial (scanning) device, so that only one mass at a time can be detected. Second, it has a limited mass range ( $<1000$  Da) and the transmission (i.e., sensitivity) decreases with mass (by at least  $\text{m}^{-1}$ ). Third, it is only possible to achieve a uniform mass resolution ( $m/\Delta m$ ) over this range of about unity. These limitations led to the introduction of energy-compensating ToF mass analyzers.

In ToF-SIMS the primary ion beam is pulsed, producing primary ion 'packets' of  $\sim 1$  ns duration. The secondary ions are accelerated over a short distance to typically 3 keV energy and injected into the ToF analyzer. In a linear ToF this is simply a field-free tube in which the ions of different mass travel with different velocities and separate, to arrive at a detector sequentially. The flight time is related to the square root of the mass, so the 'time spectrum' can be converted to a mass spectrum by suitable calibration. The mass analysis, which takes  $<200 \mu\text{s}$ , is carried out between primary ion pulses. The spectrum is therefore acquired in parallel and the ion dose is minimized. The secondary ions leave the surface with an energy distribution that, whilst only a few percent of the energy after acceleration, is enough to degrade the mass resolution. Different ToF designs compensate for this initial energy distribution in different ways, but modern instruments achieve  $m/\Delta m$  of 10k or more. The mass range is theoretically infinite, but in practice the difficulty of registering the arrival of very large slow ions gives an upper limit of  $\sim 10$  kDa. For most polymer surface studies an upper mass of 2 kDa is more than sufficient and over this range the transmission is independent of mass. Overall, the ToF approach has a  $10^4$  increase in sensitivity compared to a QMS.

The pulsed nature of ToF-SIMS provides a further benefit for the analysis of insulating materials. These charge-up under positive ion bombardment and stabilizing the surface potential is essential, otherwise secondary ion detection is rapidly curtailed. In ToF-SIMS this is efficiently achieved by irradiating the sample with a broad flood of low-energy electrons (typically 20 eV) between each primary ion pulse. This is especially important during high spatial resolution imaging (which is virtually impossible with a QMS because the ion beam current density is much higher and continuous). Because of all these advantages, ToF-SIMS is the preferred method for polymer

surface analysis and during the last decade the QMS approach has been eclipsed.

A variety of ion sources are used in ToF-SIMS. Electron impact sources are used to produce  $\text{Ar}^+$ ,  $\text{Xe}^+$ , and  $\text{SF}_5^+$ . Surface ionization sources produce  $\text{Cs}^+$ . Both of these types of source are used mainly for spectroscopy where spatial resolution is not important (although beam diameters of a few tens of micrometers are used). Liquid metal ion sources produce  $\text{Ga}^+$ ,  $\text{In}^+$ , and, most recently,  $\text{Au}^+/\text{Au}_2^+/\text{Au}_3^+$ . These sources allow the production of highly focused beams with diameters down to 30 nm. There is an advantage to using high mass primary ions since the efficiency of production of large organic fragments (i.e., the secondary ion yield divided by the primary ion dose) increases significantly with primary ion mass at any given ion energy.

An important aspect of imaging by ToF-SIMS is the ability to store (in memory) the whole spectrum for each pixel in the scanned array. This large dataset, called a raw data file, can then be interrogated retrospectively. Two smaller data files are first created: one in which all the spectral intensity is summed for each pixel to generate a total intensity image and another in which the spectra from each pixel are summed to generate a total or average spectrum. The intensity variation in the total image is due to both topography effects (as in SEM) and major compositional differences. Regions of interest can be selected by bounding a number of pixels and the spectrum from them recreated – retrospective microanalysis. From the total spectrum, peaks of interest can be selected (singly or collectively) and the intensity in all pixels displayed – retrospective chemical imaging or mapping. Thus, two scans over the field of view to collect both positive and negative ion raw data files capture all the available information.

## Spectral Features and Information

### Detection of Elements

Modern, high mass resolution, ToF-SIMS instruments make this task relatively easy. With the standard isotopic mass defined for  $^{12}\text{C} = 12.0000$ , all the elemental isotopes from  $^{16}\text{O}$  (15.9949) upward have masses slightly below the nominal unit mass. Organic fragments, being largely composed of carbon and hydrogen ( $^1\text{H} = 1.0078$ ), have exact masses that are slightly above the nominal unit mass. Thus, for example, the single isotope of  $\text{Mn}^+$  ( $^{55}\text{Mn} = 54.9380$ ) would have a serious interference with a common hydrocarbon fragment, of the same nominal mass,  $\text{C}_4\text{H}_7^+$  (exact mass = 55.0548). However, with a mass resolution of only 1500 (defined as

$m/\Delta m$ , where  $\Delta m$  is the full-width at half-maximum peak intensity) these two peaks are completely resolved. Modern instruments can usually deliver a mass resolution well above this figure, even for insulating samples that pose some problems because of surface texture or shape, and  $m/\Delta m$  of  $> 3000$  would be expected. Hence, the identification of elemental species is usually straightforward.

Hydrogen is detected with high yield with both polarities but most other elements of interest are detected in the negative ion spectrum. Carbon is detected as  $\text{C}^-$ , but the accompanying  $\text{CH}^-$  is always more intense. Similarly, oxygen is detected as  $\text{O}^-$  and  $\text{OH}^-$ . The relative intensity ratio  $\text{OH}^-/\text{O}^-$  is much more variable (structure dependent) than  $\text{CH}^-/\text{C}^-$ . The halogens give very high negative ion yields. When present in high concentration and with the appropriate structural proximity they may be observed as addition fragments  $\text{X}_2^-$  and  $\text{X}_3^-$ . Nitrogen is not usually detected as an elemental peak at  $m/z$  14 but rather as a combination ion,  $\text{CN}^-$  and additionally  $\text{CNO}^-$  if the structure is appropriate. Oxidized nitrogen functions produce  $\text{NO}_2^-$  and  $\text{NO}_3^-$ . Sulfur is detected as  $\text{S}^-$  (interfering  $\text{O}_2^-$  can usually be neglected) and  $\text{SH}^-$ . Oxidized sulfur appears as  $\text{SO}_x^-$  ( $x = 1-4$ ) and  $\text{SO}_4\text{H}^-$ . Phosphorus is usually present in the oxidized state and detected as  $\text{PO}_2^-$  and  $\text{PO}_3^-$ .

### Polymer Spectra

The interpretation of polymer spectra has been the subject of a significant body of literature. The *Static SIMS Library* contains ToF-SIMS spectra of some 200 reference polymers together with the structures of characteristic fragments. The following is, therefore, intended only to illustrate some general principles.

**Hydrocarbon polymers** Figure 2 shows the positive ion spectrum from high-density polyethylene,  $(\text{CH}_2\text{CH}_2)_n$ . Each cluster of peaks is due to  $\text{C}_n\text{H}_m^+$  where  $m = n, \dots, 2n + 1$ . For more complex aliphatic hydrocarbon polymers with pendant groups the smooth decrease in intensity of the clusters from  $\text{C}_2$  is interrupted, and the relative intensities of the ions within each cluster changes, as certain alkyl ions with methyl substituents are resonance-stabilized. Unsaturated aliphatic hydrocarbon polymer spectra are additionally characterized by a general weighting of intensity within each  $\text{C}_n\text{H}_m^+$  cluster toward lower values of  $m$  compared with saturated analogs.

The positive ion spectra of aromatic hydrocarbon polymers are exemplified by that of polystyrene in Figure 3. Compared to the aliphatic hydrocarbon spectra the  $\text{C}_n\text{H}_m^+$  clusters extend to much higher

**Figure 2** Positive ion ToF-SIMS spectrum from high-density polyethylene. (Reproduced with permission from Vanden Eynde X (2001) Quantitative analysis of polymer surfaces. **Figure 3** Positive ion ToF-SIMS spectrum from polystyrene in the mass range  $m/z=0-200$ . (Reproduced with permission from Briggs D (1998) *Surface Analysis of Polymers by XPS and Static SIMS*. Cambridge: Cambridge University Press; © Cambridge University Press.)

masses and have much lower  $m/n$  ratios as expected from the higher degree of unsaturation. Most of the prominent peaks are due to cyclic and polycyclic hydrocarbon ions, with the cyclic tropylium ion,  $C_7H_7^+$

( $m/z$  91), the most diagnostic. The negative ion spectra of all hydrocarbon polymers are very simple.  $C_1$  and  $C_2$  clusters dominate and above  $C_4$  (aliphatic) or  $C_6$  (aromatic) clusters the spectra are very weak. The

$C^-/CH_2^-$  ( $m/z$  12/14) intensity ratio is significantly higher for aromatic hydrocarbons compared with aliphatic hydrocarbons (saturated or unsaturated).

**In-chain functionality** In the spectra of hydrocarbon polymers there is no obvious manifestation of the repeat unit chemistry. Introduction of in-chain functionality changes the situation. **Figure 4** shows the positive ion spectrum of nylon-6 (polycaprolactam),  $[(CH_2)_5CONH]_n$ , where the amide function interrupts a hydrocarbon backbone. In addition to mainly hydrocarbon fragments at low

mass, a prominent series of peaks appears due to multiple repeat unit fragments  $[nM + H]^+$  where  $M$  is the repeat unit mass (113 Da). This behavior is much more typical of polymer spectra with multiple repeat unit fragments visible in either positive or negative ion spectra, or both, depending on the specific chemistry and opportunity for large stable fragment ion formation. (The relative intensity of these high mass ions is somewhat unusual in this case but they, in general, can be dramatically enhanced by the use of a polyatomic primary ion, such as  $SF_5^+$ .)

**Figure 4** Positive ion ToF-SIMS spectrum from nylon 6 (polycaprolactam). Highlighted peaks represent multiple repeat unit fragments  $[nM + H]^+$  from  $n = 1$  ( $m/z$  114) to  $n = 9$  ( $m/z$  1018). (Reproduced with permission from Briggs D (1998) *Surface Analysis of Polymers by XPS and Static SIMS*. Cambridge: Cambridge University Press; © Cambridge University Press.)

Main-chain oxygen functionalized polymers also behave in this way. Thus, linear polyethers give series such as  $[nM + H]^+$  and  $[nM + OH]^-$ . In-chain polyesters either of the poly(lactone)  $(R-COO)_n$ , or the poly(diacid-diol)  $(R_1COOR_2COO)_n$  types give series such as  $[nM + H]^+$  and  $[nM - OH]^-$ , with probable  $R-C\equiv O^+$  structures, and  $[nM + H]^-$  and  $[nM + OH]^-$ , with probable  $R-COO^-$  structures. Of course, there are many other ions formed by fragmentation at other points in the chain.

**Side-chain functionality** Several classes of polymers consist of a hydrocarbon backbone with an oxygen-containing side chain. Collectively, they can be grouped into vinyl and acrylic polymers. Vinyl polymers have the general structure  $(CH_2CHX)_n$ . In poly(vinyl ethers)  $X = -OR$ , in poly(vinyl ketones)  $X = -C(=O)R$ , and in poly(vinyl carboxylates)  $X = -OC(=O)R$ . These polymers give positive ion spectra with hydrocarbon contributions from the backbone and from the side chain R group if this has a significant number of carbon atoms (especially if linear). Repeat unit ions are observed for the ethers but the dominant ions for the other polymers tend to be side chain fragments, especially  $R-C\equiv O^+$ . In the negative ion spectra, repeat unit ions are seen for the ketones,  $RO^-$  dominates in the case of the ethers and  $RCOO^-$  dominates in the case of carboxylates.

Acrylic polymers are based on esters of acrylic acid and methacrylic acid and co-polymers are very common. Figure 5 shows the positive ion spectrum of poly(methyl methacrylate) (PMMA). Compared with the other oxygen-containing side-chain polymers just discussed the spectrum appears to be influenced to a greater extent by hydrocarbon fragments from the backbone. However, at high mass resolution, most peaks are seen to be multicomponent, often with a hydrocarbon component, but frequently due only to oxygen-containing fragments – some examples are illustrated in Figure 6. Interesting repeat unit fragments are even-mass radical cations (e.g.,  $m/z$  126, 154, 196, 200); these appear as essentially single-component peaks as illustrated by  $m/z$  126 in Figure 6. With higher methacrylates (R larger than  $CH_3$ ) the positive ion spectrum becomes more hydrocarbon-like. The common diagnostic ion is the methacryloyl ion at  $m/z$  69.

The negative ion spectrum of PMMA is shown in Figure 7. With the absence of 'hydrocarbon noise' this is a much simpler spectrum and the pattern of peaks clearly reflects the repeat unit mass of 100 amu. Negative ion peaks characteristic of all methacrylates, because the side-chain alkyl group (R) has been lost, are at  $m/z$  85, 109, 125, and 139.

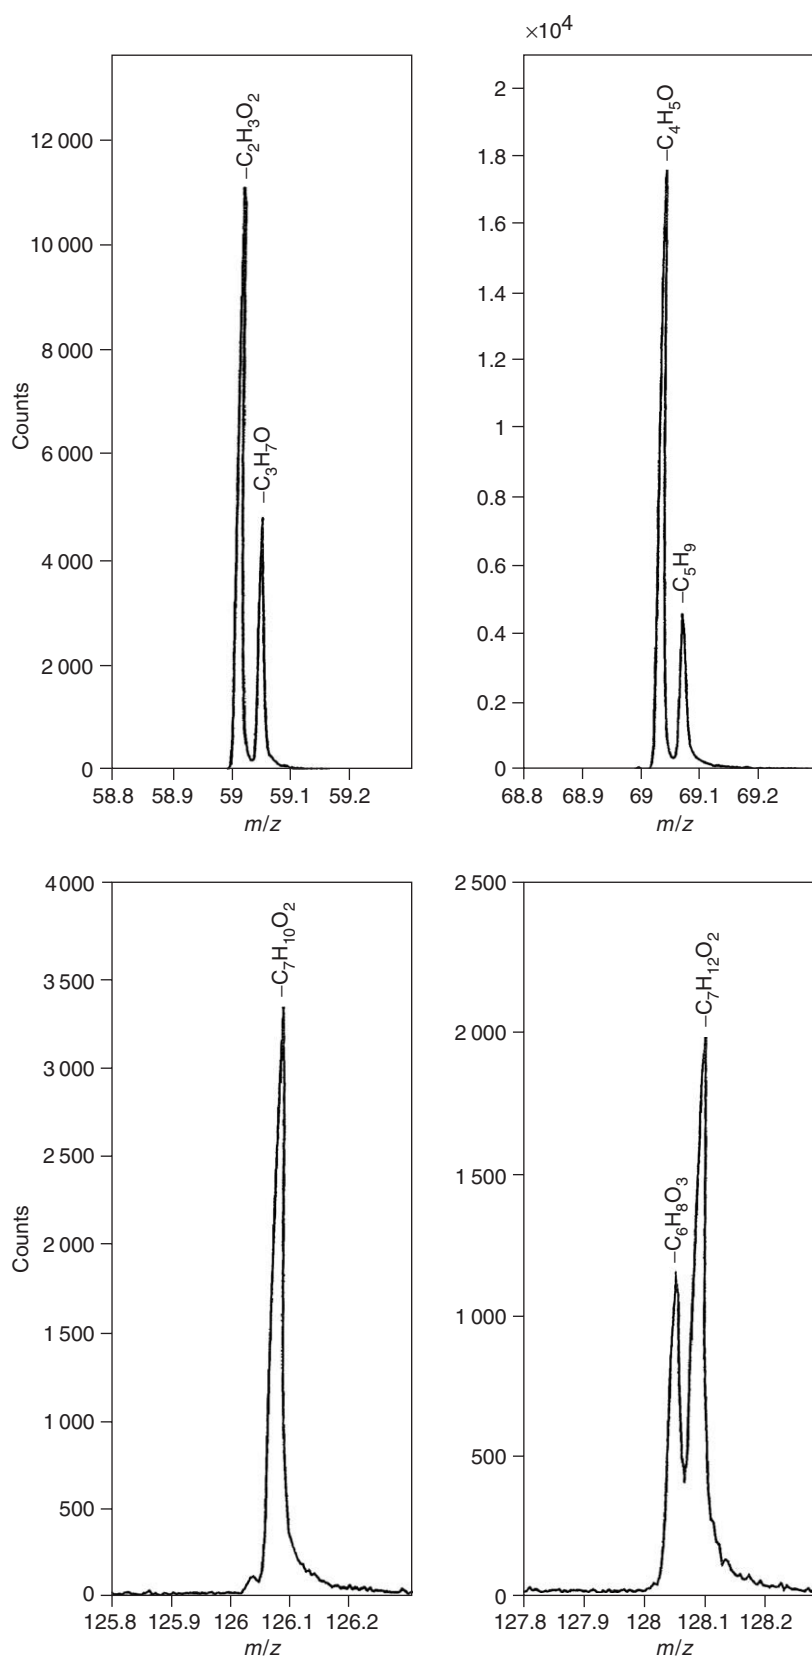

**Figure 5** Positive ion ToF-SIMS spectrum from poly(methyl methacrylate) in the mass range  $m/z = 0-200$ . (Reproduced with permission from Briggs D and Fletcher IW (1997)  $Cs^+$  ion beam damage of poly(vinyl chloride) and poly(methyl methacrylate) studied by high mass resolution ToF-SIMS. *Surface and Interface Analysis* 25: 167–176; © John Wiley & Sons Ltd.)

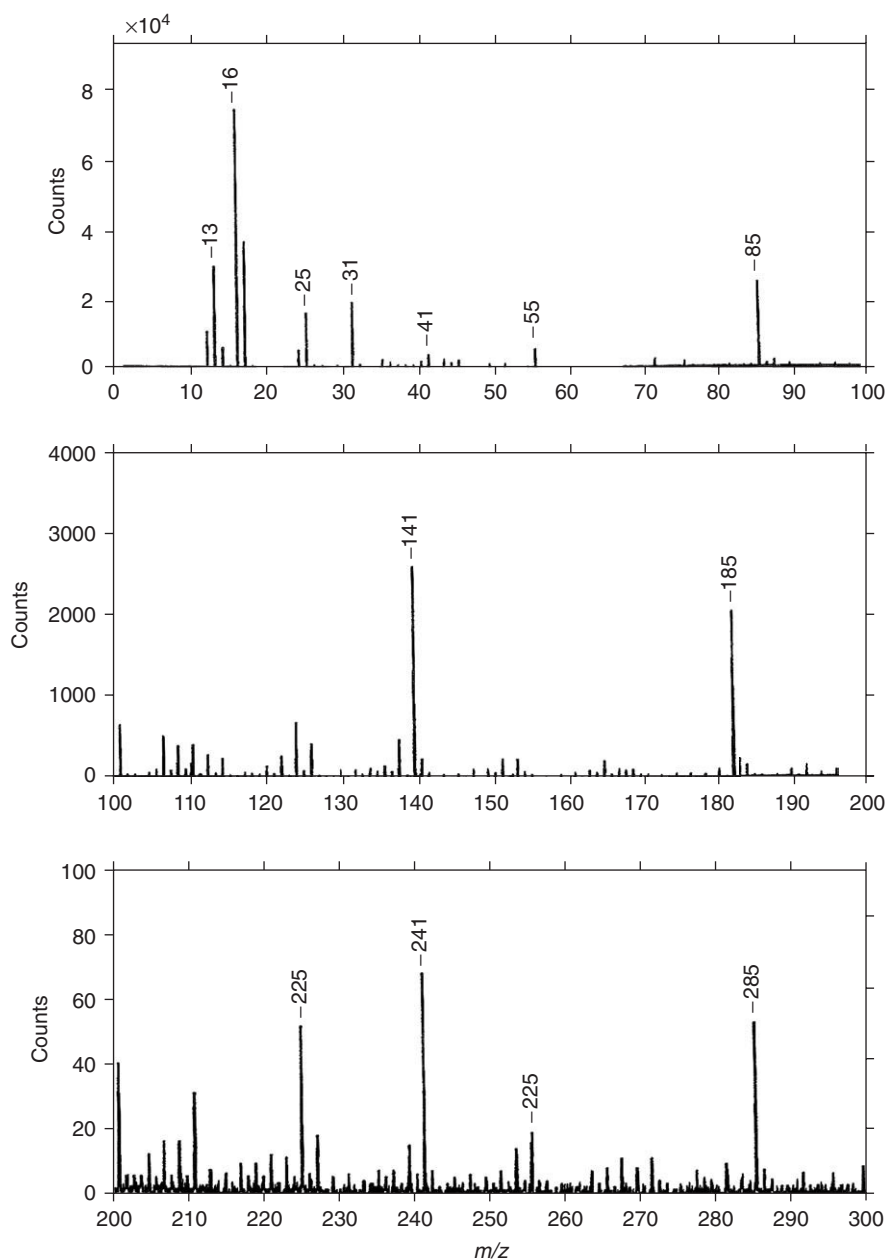

Specific ions having one or more intact side chains have the generic formulae:  $[M + 55]^-$ ,  $[2M - 15]^-$ ,  $[2M + 41]^-$ ,  $[2M + 55]^-$ , and  $[3M - 15]^-$  where  $M$  is the monomer mass. In the PMMA spectrum these are at  $m/z$  155, 185, 241, 255, and 285.

Acrylate homopolymers behave similarly, except that the repeat unit ions are much less stable. The characteristic common positive fragment is the acryloyl ion at  $m/z$  55. Common negative ions appear at  $m/z$  65, 67, 71, and 81, whilst specific ions are  $[M - H]^-$ ,  $[M + 13]^-$ ,  $[M + 27]^-$ ,  $[M + 39]^-$ , and  $[M + 53]^-$ .

The spectra of random acrylic co-polymers display the monomer-specific features of the components together with fragment ions that reflect the linking of the different monomers in the chain. These are the equivalent of the multiple repeat unit ions from a homopolymer, but now the monomers need not be the same. In all cases the negative ion spectra are the most informative. Thus, for example, the  $[2M - 15]$  ion from a methacrylate homopolymer could appear as  $[2M_1 - 15]^-$ ,  $[2M_2 - 15]^-$ , or  $[M_1M_2 - 15]^-$ , where  $M_1$  and  $M_2$  are the two monomers in a random co-polymer. The spectra of co-polymers in general are discussed in more detail below.

**Figure 6** High mass resolution details of some of the peaks in **Figure 5**. **Nitrogen-containing polymers** The polyamide nylon-6 has been discussed above. Other polylactams behave similarly and display a characteristic pair of peaks at  $[2M + \text{H}]^+$  and  $[2M - \text{OH}]^+$ . Diacid-diamine polyamides,  $(\text{R}_1\text{CONHR}_2)_n$ , show some similarity to in-chain polyesters having dominant fragments of the type  $\text{R}-\text{C}\equiv\text{O}^+$ . However, since there is no equivalent of the  $\text{RCOO}^-$  ion from nylons, the negative ion spectra are usually lacking in

high mass molecular fragments. The characteristic peaks are simply  $\text{CN}^-$  and  $\text{CNO}^-$ . Nitrogen content is generally obvious from the positive ion spectra through the higher than normal incidence of even mass peaks (due to fragments with one, or an odd number of, N atoms).

Another important class is the polyurethane, where a polyether,  $(\text{X})_n$ , is reacted with a di-isocyanate (in this case MDI) and chain extended with either

a diamine or a diol (Y). The positive ion spectrum is principally a superposition of the polyether spectrum (discussed above) and fragments of the di-isocyanate. In the case of 4,4'-methylenebis(phenylene isocyanate) (MDI), characteristic peaks are at  $m/z$  106, 132, 180 and 233. The polyether can be replaced by a polyester in which case its spectrum will be a significant component of the polyurethane spectrum.

**Halogen-containing polymers** These polymers are characterized by intense negative ions from the halogen. Aliphatic chlorine-containing polymers such as poly(vinyl chloride)  $(\text{CH}_2\text{CHCl})_n$  give positive ion spectra that at first sight resemble hydrocarbon spectra. However, at high mass resolution many peaks are seen to have additional components containing one or two Cl atoms.

Highly fluorinated polymers give an intense  $\text{CF}_3^+$  peak at  $m/z$  69, even if this group is not present in the molecule. Poly(tetrafluoroethylene)  $(\text{CF}_2\text{CF}_2)_n$  gives generic fragments  $\text{C}_x\text{F}_y^{+/-}$  and poly(vinylidene fluoride)  $(\text{CH}_2\text{CF}_2)_n$  gives generic fragments  $\text{C}_x\text{F}_y\text{H}_z^{+/-}$ . An important class of lubricants is the perfluoropolyethers. These are homo- or co-polymers involving the units  $(\text{CF}_2\text{O})$ ,  $(\text{CF}_2\text{CF}_2\text{O})$ , and  $(\text{CF}_2\text{CF}(\text{CF}_3)\text{O})$ . Complex repeat unit sequences are seen in both polarity spectra with characteristic low mass ions being  $\text{CFO}^+$  ( $m/z$  47) and  $\text{CF}_3\text{O}^-$  ( $m/z$  85). Low molecular weight materials with the same repeat units are often differentiated by their end groups, which give diagnostic peaks.

**Aromatic polymers** Apart from hydrocarbon polymers containing styrene, discussed above, this is a large class of polymers. Attachment of heteroatoms to the phenyl ring, either in-chain or in a pendant group, leads to characteristic ions. Thus, ring-substituted styrene polymers give substituted tropylium ions,  $\text{C}_7\text{H}_6\text{X}^+$  (e.g.,  $\text{X} = \text{OH}$ ,  $\text{F}$ ,  $\text{Cl}$ ,  $\text{Br}$ ), and aromatic polyethers give  $\text{C}_6\text{H}_5\text{O}^-$ .

**Silicones** Silicone rubbers and oils are usually based on polydimethylsiloxane  $(\text{Si}(\text{CH}_3)_2\text{O})_n$ . They all give spectra readily identified through the positive ions at  $m/z$  28, 47, 147, 107, 221, and 281. The relative intensities of these peaks vary as a function of molecular weight, end groups, and cross-link density in the rubbers.

### Organic Molecules on Polymer Surfaces

Probably the most important aspect of ToF-SIMS analysis involves the use of the technique to understand the variation in surface properties, such as

wettability, adhesion, and friction, which are sensitive to submonolayer coverage of molecular species. ToF-SIMS is unique in its sensitivity and molecular speciation capability. However, unlike the situation with gas-phase organic molecule identification by electron impact mass spectrometry there are, as yet, no well-established 'rules' that allow molecular identification directly from the spectra. The situation is also complicated, in most cases, by the superposition of the spectrum of the substrate and the potential presence of more than one organic molecule.

Organic molecules usually give quasimolecular ions of the type  $[\text{M} + \text{H}]^+$  and  $[\text{M} - \text{H}]^-$ , where  $\text{M}$  is the molecular weight, in addition to characteristic fragments. In the case of polymer substrates, the intensity from the substrate spectrum is, typically, only high in the region  $m/z$  0–200. Quasimolecular ions are usually of higher mass, and even though their absolute intensity may be rather low, they are easily observed relative to the contribution from the substrate. An example is given in Figure 8, which shows the positive ion spectrum from the surface of pretreated (electrochemically oxidized) polypropylene. Below  $m/z$  120 the spectrum is essentially due to hydrocarbon polymer fragments (compare with Figure 1). Higher mass peaks are due to contamination and segregated additive molecules. The phosphite antioxidant Irgafos 168 gives rise to a distinctive set of peaks around  $m/z$  650. Although  $[\text{M} + \text{H}]^+$  for the phosphite is expected at  $m/z$  647 it is believed that the spectrum is mainly due to the oxidized phosphate product (the molecule is present to decompose hydroperoxides), which would give  $[\text{M} + \text{O} + \text{H}]^+$  at  $m/z$  663.

Pattern recognition is the key to organic molecule identification. Common 'surface contamination' molecules fall into a relatively small number of chemical families, depending on their function, e.g., surfactants, lubricants, and the various types of polymer additives (plasticizers, antioxidants, etc.). Thus, many surfactants are based on quaternary ammonium salts, many plasticizers are dialkyl phthalates, most antioxidants are di-*t*-butyl phenol derivatives, etc. The result is that each family member is likely to give a spectrum with some common fragment ions whilst having unique molecular ions. Alternatively, the whole spectrum may conform to a particular pattern but with components 'shifted' by fixed mass intervals, e.g., fatty acids that have a common hydrocarbon series in the positive ion spectrum plus molecular ions/fragments that increase in mass by 14 amu ( $\text{CH}_2$ ) as the homologous series is ascended. The easiest way to recognize these patterns is to study the collections of relevant spectra, collated by function, in *The Static SIMS Library*.

**Figure 8** Positive ion ToF-SIMS spectrum from the surface of pretreated (electrochemically oxidized) polypropylene, illustrating the typical signal-to-noise ratio of polymer fragments at low mass and additive molecular ions at high mass (see text). The peak at  $m/z$  133 is due to primary  $\text{Cs}^+$  ions. (Reproduced with permission from Vanden Eynde X (2001) Quantitative analysis of polymer surfaces. In: Vickerman JC and Briggs D (eds.), *ToF-SIMS: Surface Analysis by Mass Spectrometry*, Ch.16. Manchester: SurfaceSpectra/IM Publications; © SurfaceSpectra/IM Publications.)

## Quantitative Aspects

SIMS is an inherently nonquantitative technique – there is no direct relationship between peak intensity and the concentration of the species it represents. This is because secondary ion yields are strongly dependent on the chemical environment (or matrix), examples of which were noted in the previous section. Matrix effects in SIMS are most notable for yields of elemental species from inorganic matrices, but the situation is less severe for polymer matrices. Thus, relative intensities such as  $\text{O}^-/\text{CH}^-$  or  $\text{F}^-/\text{CH}^-$  correlate with X-ray photoelectron spectroscopy (XPS) atomic ratios (O/C, F/C) when trends in composition are restricted to similar materials; however, the  $\text{Cl}^-:\text{CH}^-$  ratio for a variety of chlorine-containing polymers does not correlate with the XPS Cl/C atomic ratio.

There have been many quantitative studies of co-polymers, in which the intensities of fragments

representing monomers or larger units have been correlated with composition. An early example, shown in **Figure 9**, concerns random hydroxyethylmethacrylate/ethylmethacrylate (HEMA/EMA) co-polymers and the use of characteristic negative ions (as discussed above). Fragments at  $m/z$  127 and 155 are essentially representative of HEMA and EMA monomers, respectively, and relative intensity plots of the form  $A/A + B$  give smooth trends (upper curves). The intensities of fragments at  $m/z$  141 and 185, believed to represent HEMA–EMA linked monomers (middle curves), maximize in the midrange as expected. The intensity of the fragment at  $m/z$  213, representing EMA–EMA links increases rapidly with EMA content (lower curve), also as expected. The ratio  $I(213)/I(155)$  represents the ratio of diads to singles. For a random co-polymer where diad (AA) signals come from sequences  $\text{B}-(\text{A})_n-\text{B}$  where  $n > 2$ , a statistical analysis predicts the ratio of diads to singles (isolated A units) will be proportional to the

**Figure 9** Relative intensities of characteristic negative ion fragments from HEMA-EMA copolymers (see text) plotted as function of bulk composition. Error bars in (A) represent the largest spread of values for any measurement; those in (B) and (C) represent the spread of values for all repeated measurements. (Reproduced with permission from Briggs D and Ratner BD (1988) A semi-quantitative SIMS analysis of the surfaces of random ethyl methacrylate: hydroxethyl methacrylate copolymer films. *Polymer Communications* 29: 6–8; © Butterworths.)

mole fraction of A, as seen in the lower plot. The choice of fragments for such plots is not always so obvious and in many cases better results are obtained by using multivariate statistical analysis techniques that utilize the whole spectrum.

The end groups of a polymer can have a marked effect on the SIMS spectra. If these are chemically distinct from the rest of the chain, because of the use of specific initiation or termination reactions, they will give rise to readily identifiable peaks. However, in all cases end groups can have a disproportionate effect on spectra because only one bond needs to be broken to produce a fragment whereas two bonds need to be broken to generate an in-chain fragment. Ratios of fragments due to end groups and in-chain fragments in homopolymer spectra depend on molecular weight, typically up to 20–30k. This provides a unique method for monitoring surface average molecular weight, which can be particularly important in this range. Low molecular weight fractions of the distribution may migrate to the surface and significantly alter mechanical properties relative to the bulk polymer as well as leading to adverse surface behavior.

## Secondary Neutral Mass Spectrometry

**H Oechsner**, Universität Kaiserslautern, Kaiserslautern, Germany

### Introduction

The removal of atoms and molecules from a solid surface with 'atomic spoons' and their subsequent mass spectrometric identification constitutes the most direct method of determining the surface composition of a solid. In practice, the ejection of surface particles is achieved by bombardment with primary atomic species, mostly ions, a process generally referred to as 'sputtering'. It is well established both by real and computer experiments that for moderate bombarding energies up to the lower keV regime particle ejection occurs mainly from the topmost atomic layer or, with rapidly decreasing probabilities, from a very shallow depth of a few atomic distances beyond the surface, thus providing information that is extremely surface sensitive.

It has been well established that the vast majority of the ejected surface particles consists of neutrals. Secondary ions contribute to the ejected particle flux at most to some  $10^{-2}$  for ionic targets as metal oxides, but remain by orders of magnitude lower in most other cases. Nevertheless, secondary ions have long been utilized for surface analysis (secondary ion mass spectrometry, SIMS), since they can immediately be identified in mass spectrometers employing electric or magnetic fields for particle separation. However, the ionization probability during the ejection process has also long been recognized to depend strongly on the chemical environment at the ejection site. Hence, SIMS signals are generally subjected to strong matrix influences that are difficult to take into account quantitatively, and, therefore, usually prevent quantitative information about the composition of an unknown sample surface from being derived. Deleterious matrix effects can be avoided to some extent by transforming the surface into a new distinct chemical state, e.g., by oxidizing it through oxygen flooding or a sufficiently dense bombardment with oxygen ions as primary particles. More recently, the signals of  $\text{MCs}^+$  ions produced under bombardment with  $\text{Cs}^+$  primary ions have also proved to be less matrix sensitive.

Such disadvantages clearly do not exist when the dominating neutral particle flux from an ion bombardment surface is evaluated. Even when the usually

very low secondary ion yields vary by orders of magnitude with changing surface concentrations, the flux of sputter ejected neutrals remains stable and reflects the true surface composition. In order to allow their mass spectrometric identification the ejected neutral atoms and molecules must, however, be 'postionized' in an appropriate way. Such experimental complications were the main reason why secondary (or 'sputtered') neutral mass spectrometry (SNMS) has been introduced as a surface analytical technique much later than SIMS. The main difference between these two techniques is clearly that particle ejection and ionization occur in the same event in SIMS, but are strictly separated in SNMS. This means that in SNMS, for appropriate performance, the particle-specific postionization probability becomes a constant of the analytical apparatus. This makes quantification of SNMS, i.e., the correlation between the mass spectrometric signals and the surface concentration of the respective particle, straightforward and simple.

Among the possibilities available to postionize sputter-ejected neutral surface particles, electron impact ionization has been employed in a variety of experimental approaches. More recently, photoionization by resonant or nonresonant multiphoton absorption processes has been established as another very effective technique in SNMS. Other processes as Penning ionization or charge exchange play only a minor role in postionization for SNMS.

Because of its attractive features SNMS is expected to replace SIMS when quantitative analysis of inhomogeneous samples and of layered structures is required. SNMS microprobes both based on electron impact postionization and photoionization enable microanalysis with the full quantifiability of this technique. While SIMS is quantitatively applicable only when the analyte is diluted in a homogeneous matrix at concentrations sufficiently below 1 at.%, i.e., when each secondary ion is emitted from an identical chemical environment, SNMS is an appropriate analytical technique across the entire concentration range varying from values close to unity down to well below the ppm level. For a comparison with electron spectroscopic techniques as Auger or photoelectron spectroscopy (AES or XPS), one has to consider that the original surface composition is in general changed under ion bombardment owing to preferential particle removal or atomic mixing effects. AES and XPS are monitoring such altered surface compositions. In contrast, SNMS collects

with a specific but constant detection efficiency the sputter-removed particles, thus providing quantitative information about the original sample composition.

The following sections will deal first with the physical effects involved in postionization, then with the respective instrumentation, and finally with the quantification schemes in surface and depth profile analysis with SNMS. A critical comparison of the different SNMS techniques will be addressed where appropriate.

## Postionization of Sputtered Neutral Particles

Historically, the first attempts to postionize sputter-released particles were performed with electron beam arrangements. Similar to residual gas analysis (RGA), an electron beam ionizer was placed between the sputtered surface and the entrance of a mass spectrometer. Compared with RGA very moderate postionizing efficiencies in the order of  $10^{-5}$ – $10^{-6}$  ionized particles per neutral sputtered particle entering the ionizer have been achieved, resulting in very low mass spectrometric signals and, hence, a low detection power. Such unattractive features, which are essentially due to the very short dwell time of sputtered particles in the ionizing electron beam, ensured an almost negligible interest in SNMS. It was found only after those first SNMS attempts that the energy distribution of sputtered particles is determined by the relatively violent atomic collisions in the sputtering cascades. The influence of the surface binding energy  $U_0$ , which in general is in the order of several eV, causes the energy distributions of sputtered atoms to peak at several eV (more precisely at  $U_0/2$  for a fully developed isotropic sputter cascade) and the average energy of sputtered atoms to be in the region of 10 eV, thus making the particles to be postionized very fast.

A considerably more effective way of electron impact postionization for mass spectrometric identification of sputtered neutral species was introduced by employing a spatially expanded hot Maxwellian electron gas (see below). Much higher postionization efficiencies of the order of  $10^{-2}$  were established by this method for which the acronym SNMS was first introduced.

Both for electron beam and electron gas postionizations the efficiency  $\alpha_x^0$  for postionizing a sputtered species  $X$  is described by

$$\alpha_x^0 \sim n_e l \iint Q_x(v_e) f(v_e) v_e N_x(v_x) v_x^{-1} dv_e dv_x \quad [1]$$

where  $f(v_e)$  is the electron velocity distribution,  $Q_x(v_e)$  the ionization function of  $X$ , and  $N_x(v_x)$  the

velocity distribution of the sputtered species to be ionized.  $\alpha_x^0$  is proportional to the electron density  $n_e$  and the individual dwelling times  $t_x = 1/v_x$ . For electron beam postionization the distance  $l$  along which postionization occurs is determined by the beam diameter and  $f(v_e)$  is a narrow distribution around the nominal beam velocity that can be matched to the maximum of  $Q_x$ , i.e., the maximum total cross-section for electron impact ionization of an individual species  $X$ . In the electron gas mode  $l$  is the traveling length of sputtered particles through the postionization electron gas (typically in the order of 5 cm), and  $f(v_e)$  is in general a Maxwellian distribution with a maximum corresponding to an electron energy of  $\sim 10$  eV. The ionization functions  $Q_x(v_e)$ , starting at the respective ionization threshold energy (a few eV), display a broad maximum at electron energies of 50–100 eV. Hence, both the much larger traveling distances  $l$  and the broader overlap between  $f(v_e)$  and  $Q_x(v_e)$  are the main reasons for the much higher ionization efficiencies  $\alpha_x^0$  for electron gas compared with electron beam postionization.

With the availability of high power lasers providing up to a few 100 mJ for nanosecond and to a few 10 mJ for picosecond pulses, photoionization based on resonant or nonresonant multiphoton absorption schemes can be employed as another effective postionization technique. Ionization efficiencies close to unity are achieved when a resonant step is included in the multiphoton absorption process (resonant-enhanced multiphoton ionization, REMPI). REMPI provides unrivalled detection sensitivity when the photon energy is tuned to a resonant step for the specific atomic energy structure of the species to be detected. REMPI has also been successfully employed to sputtered organic molecules. Nonresonant multiphoton ionization (NRMPI) has first been developed for the analysis of inorganic samples (surface analysis by laser ionization). Saturation of all photoion signals for the different species in the sputtered particle flux can be achieved in nonresonant schemes for laser intensities in the  $10^{12} \text{ W cm}^{-2}$  regime. Quasiresonant intermediate atomic states may become effective in such cases also. Below saturation, the dependence of the NRMPI signals of the laser intensity (or the photon density in the ionizing volume) was not always found to follow the expected power law, for instance, a quadratic dependence for two photon processes. The respective deviations may in part be referred to contributions from photon-induced dissociative ionization of the molecule fraction in the particle flux from the sample. Because of the reduced photon density in the edge regions of the laser beam such influences may

prevail, even when atomic photoionization in the center of the beam profile becomes saturated.

Postionization via a Penning process, i.e., by the interaction of a sputtered particle with a metastable atom as, e.g.,  $\text{Ar}(^3\text{P}_{2,0})$  with a stored energy of 11.5 or 11.7 eV, necessarily requires a high collision rate between heavy particles in an appropriate gas discharge. The corresponding analytical technique known as glow discharge mass spectrometry (GDMS) employs direct current (DC) or radio frequency (RF) discharges maintained in a noble gas at pressures of the order of  $10^{-2}$ – $10^{-1}$  mbar. The collisional interactions being necessary for the Penning process destroy the kinetic properties of the sputtered released surface particles, and lead to the formation of new molecular species (e.g., 'argides') by associative ionization. The latter effect may seriously hamper the quantification of the GDMS spectra from an unknown sample. Backscattering of previously sputter-removed particles to the sample via elastic collisions reduces depth resolution during thin film analysis. Since GDMS is in general more considered as a technique for bulk analysis and in general not compatible with ultrahigh vacuum (UHV) conditions, it will not be discussed further in the context of this article.

## Instrumentation for SNMS

### Electron Beam Postionization

After the advantages of SNMS for quantitative surface analysis had been recognized, a number of improved systems for electron beam postionization were developed. A corresponding setup is schematically depicted in Figure 1. Such an arrangement can be used either for SIMS or SNMS studies alternatively by switching off or on the postionizing electron beam from an electron-emitting filament. Typically, electron energy of 50–80 eV is used for postionization purposes in e-beam SNMS employing total electron currents up to a few mA. Typical cross-sections of the electron beam in such arrangements are at best in order of several  $\text{mm}^2$ . In order to suppress the secondary ions sufficiently, a retarding voltage in the order of 100 V is applied between the sample and the mass spectrometer entrance. Otherwise it is possible that higher secondary ion signals influenced by the already mentioned matrix effects would superimpose on the corresponding SNMS intensities. Since an arrangement such as sketched in Figure 1 acts simultaneously as a residual gas analyzer, the postionized sputtered particles have to be separated from the thermal residual gas ions that are ionized with much higher efficiency because of their

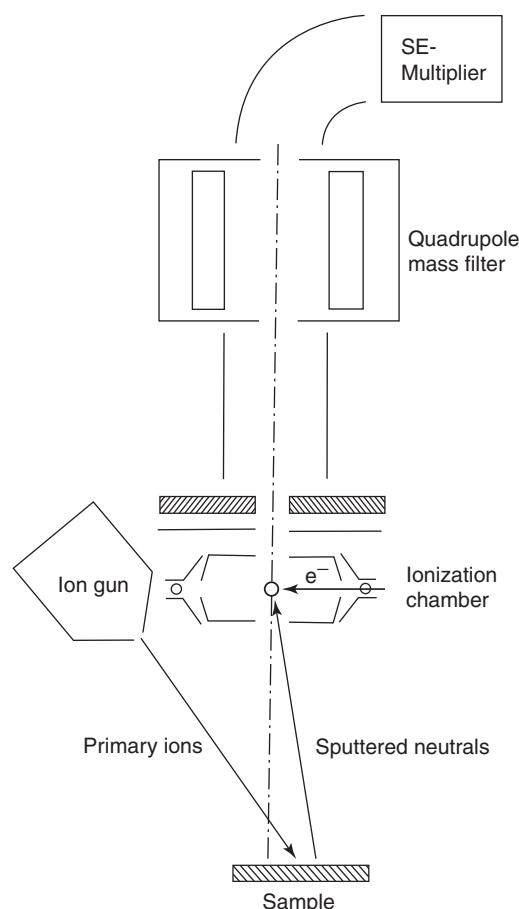

Figure 1 Schematic setup for electron beam SNMS.

low kinetic energy. This is achieved by another potential step between the ionization chamber and the mass spectrometer. The height of this potential step has to be adjusted such that the low-energy residual gas ions are retarded and only the faster fraction of postionized sputtered particle flux can enter the mass analyzer. Background signals can be reduced to a level of  $10^{-8}$  of the SNMS signals with an additional deflection capacitor between the residual gas suppression and the mass spectrometer and by choosing the bombarded spot at the sample surface slightly outside of the ion optical axis. In any case, one has to consider that low-energy sputtered particles from the sample surface being postionized in the electron beam can be trapped in the negative space charge well of the beam, and are thus lost for the analytical information.

### Electron Gas SNMS

Electron impact postionization with much higher efficiency is established when the sputtered neutral particles travel a longer distance through a volume

with a high density of electrons with sufficient energy. Such an 'electron gas' can be established in an effective way by the electron component of an electrodeless RF plasma maintained at gas pressures well below the usual glow discharge regime in a noble gas. Electron cyclotron wave resonance (ECWR) has proved to be a very suitable method for producing in Ar electron densities  $n_e$  of  $10^{10}$ – $10^{11}$  cm $^{-3}$  at pressures in the  $10^{-4}$ – $10^{-3}$  mbar range. Such high  $n_e$ -values are possible since the electron space charge is compensated by the background of positive plasma ions with energies only little above the thermal energies of the neutral gas particles. In contrast to the electron beam method, electron gas postionization is, therefore, not impeded by space charge effects in the ionizing volume. The electron component of an ECWR plasma in Ar was found to have a Maxwellian energy distribution with electron temperatures  $T_e$  equivalent to 10–15 eV, depending on the excitation conditions. Because of the low working pressure, heavy particle collisions can be neglected for traveling distances  $l$  of  $\sim 5$  cm that are usually employed for electron gas postionization. Plasma excitation by ECWR is well compatible with UHV conditions, and can be performed in an internal chamber inside a UHV vessel.

The layout of a commercial apparatus for electron gas SNMS is depicted in **Figure 2**. The sample head is introduced directly into the postionizing electron gas. Particle emission from the sample surface is excited by extracting ions from the ECWR plasma by a simple ion optical arrangement in front of the sample (direct bombardment mode, DBM). Since the angular distribution of sputtered particles changes from a torus-like configuration to an over-cosine behavior when the

bombarding ion energy is increased from the 100 eV regime to a few keV, the sputtered particle flux along the sample normal and, hence, the SNMS signals vary accordingly. In order to minimize the resulting element-specific dependence of the individual SNMS signals on the bombarding ion energy, a take-off angle of  $30^\circ$  against the normal to the sample is chosen. The neutral sputtered particles being postionized with an efficiency  $\alpha^0$  in the order of several  $10^{-2}$  are then guided to a quadrupole mass spectrometer via a  $45^\circ$  electrostatic deflector as an effective means to improve the signal-to-background ratio. Since the full energy distribution of the sputtered particles arrives at the entrance of the ion optical system, suppression of low-energy plasma ions can be readily established by a small positive potential step at the optics entrance. An SNMS spectrum obtained with the DBM from a sintered Mo sample is shown in **Figure 3**. The inset displays a mass interval with some low-concentration elements (or impurities) in the specimen. The retarding potential at the entrance lens of the ion optics was adjusted such that the peak of  $^{40}\text{Ar}$  ions from the ECWR plasma is reduced to the level of the main sample signals.

Whereas sample bombardment with an ion gun as employed in electron beam SNMS is usually performed at energies in the lower keV regime, much lower energies can be used in the DBM of electron gas SNMS. A schematic diagram of the corresponding ion extraction system is shown in **Figure 4**. By matching the distances  $D = X_2 - X_1$  properly for a given bombarding voltage applied between the ECWR plasma and the sample, an ideally plane plasma boundary can be established across a plane sample. Under such conditions the sample is

**Figure 2** Schematic of a commercial instrument for electron gas SNMS. (By IFOS GmbH, Kaiserslautern.)

**Figure 3** SNMS spectrum from a sintered Mo sample obtained with 1.8 keV  $\text{Ar}^+$  ions at  $2.1 \text{ mA cm}^{-2}$ .

**Figure 4** Scheme of the ion extraction system for the direct bombardment mode of SNMS.

bombarded with extremely high lateral homogeneity at very low bombarding energies down to a few tens of eV at ion current densities in the order of  $1\text{--}2 \text{ mA cm}^{-2}$ . Thus, bombardment-induced atomic mixing effects at the sample become minimized and particle ejection is confined to the uppermost atomic layer. Both the high lateral homogeneity of sputter removal and the low bombarding energy make the

DBM extremely well suited for depth profile analysis. For amorphous samples the depth resolution obtained with this technique has been shown to be limited only by the atomic microroughness extending to  $\sim 4$  atomic distances or  $1\text{--}1.5 \text{ nm}$ , which develops as a consequence of the statistical sputter removal. A section of a bombarding crater obtained under such conditions is shown in **Figure 5A**.

The analysis of insulating samples at bombarding ion energies down to 100 eV or less becomes possible with the so-called high-frequency mode (HFM) of SNMS. For this operation mode a square wave high-frequency voltage is applied to the sample instead of a constant DC voltage as employed for DBM. Such an RF voltage can be basically looked at as a DC voltage, providing constant ion optical conditions, which is switched off periodically to admit short flux pulses of plasma electrons onto the insulating sample for compensating the positive charge from the preceding ion bombardment interval. The frequency of the applied square wave RF voltage and the ratio between the time intervals for the ion and electron fluxes within each period have to be chosen such that the variation of the surface potential due to charging up during the ion bombardment interval remains negligibly small. The bombarding ion energy is then controlled by the amplitude of the square wave voltage, and the same conditions for the analysis of dielectric samples are achieved with the HFM as for conducting samples with the conventional DBM. This is demonstrated in **Figure 5B**, which shows the edge region of a bombarding crater in an electrically nonconducting glass. An SNMS spectrum obtained with the HFM technique for a completely nonconducting ceramic ( $\text{BaTiO}_3$ ) is shown in **Figure 6**. Despite the periodically interrupted ion bombardment with  $\text{Ar}^+$  ions of only 800 eV the signal intensities for the main components approach  $10^6 \text{ cps}$ . The possibility to identify low-concentration admixtures that control the dielectric constant of the material is essential in this case.

**Figure 7** depicts a schematic diagram of another operation mode of electron gas SNMS. In this 'external bombardment mode' (EBM) the sample is mounted outside the positionizing plasma chamber and bombarded with an external ion gun. Sputter-removed neutral surface particles enter the SNMS plasma through an electrical diaphragm that can be opened in any direction for charged particles of arbitrary sign. In EBM, the positive ion charge transferred to an insulating sample from the ion gun can be compensated by an electron current being extracted from the SNMS plasma through the diaphragm. The charge compensation becomes directly visible by the variation of the SNMS signals as a

**Figure 5** Edge regions of ion bombarding craters produced in amorphous Si by the DBM technique with 200 eV  $\text{Ar}^+$ , and in a nonconducting silicate glass by the HFM version of SNMS with 480 eV  $\text{Ar}^+$ .

**Figure 6** SNMS spectrum acquired with HFM-SNMS from a ceramic  $\text{BaTiO}_3$  sample containing a number of minor admixtures. (Normal bombardment with 800 eV  $\text{Ar}^+$ ; ratio between ion-to-electron flux time intervals 1:1; operation frequency 500 kHz.)

**Figure 8** SNMS depth profile of an insulating oxidic layer structure (65 nm  $\text{TiO}_2$ /90 nm  $\text{SiO}_2$ /65 nm  $\text{TiO}_2$ /float glass). Analysis with charge compensated external bombardment mode with 5 keV  $\text{Kr}^+$ .

**Figure 7** Schematic diagram of the external bombardment mode of electron gas SNMS, including an Auger electron spectrometer for complementary analysis.

function of the potentials applied to the diaphragm electrodes: Without an electron flow to the insulating sample no SNMS signals appear, since sputtering is prevented by charging-up of the sample. For an appropriate choice of the diaphragm potentials the SNMS signals appear and become stationary at well-defined diaphragm voltages, because now a

low-energy electron current from the plasma penetrates to the specimen. Exact charge neutralization can be readily determined from the point where the SNMS signals just reach their saturation values.

An SNMS depth profile of an oxidic layer structure on a float glass substrate acquired with the EBM is presented in **Figure 8**. Complete charge compensation of the 5 keV  $\text{Kr}^+$  beam scanned across the sample surface was continuously maintained when profiling through the highly insulating sample structure with a 65 nm  $\text{TiO}_2$ /90 nm  $\text{SiO}_2$ /65 nm  $\text{TiO}_2$  layer stack on a glass substrate. Interesting features as the influence of the individual interfaces acting as diffusion barriers for Na, or the surface segregation of this component, become clearly visible.

When a highly focused ion beam, for example, of  $\text{Ga}^+$  ions from a liquid metal ion source with a beam diameter of typically a few 100 nm is employed in the EBM or directed to the sample through the ECWR plasma, a secondary neutral microprobe – a competitor to the secondary ion microprobe – is established. **Figure 9** shows a layout of a secondary neutral

**Figure 9** Schematic layout of an electron gas secondary-neutral microprobe.

microprobe based on electron gas postionization. The plasma chamber is ion-optically coupled to a high transmission double-focusing mass spectrometer by a four-electrode electrostatic lens system and a dual quadrupole deflector. Such an instrument provides detection limits better than in the mg per g range when elemental surface distributions are imaged with a primary 20 keV  $\text{Ga}^+$  beam of a spot size of 1  $\mu\text{m}$ .

Although an SNMS microprobe is principally designed to obtain secondary neutral micrographs on inhomogeneous sample structures, it can also be operated in the DBM of electron gas SNMS. Because of the high transmission of the double focusing magnetic mass spectrometer, and since the mass independent background in the respective DBM spectra is below  $10^{-2}$  cps, detection limits in the nanogram-per-gram range are achieved.

### Laser SNMS

Postionization by resonant or nonresonant multiphoton absorption is mostly used in conjunction with a time-of-flight (TOF) mass spectrometer, since a postionizing laser pulse with a duration in the nanosecond, picosecond, or even subpicosecond regime provides an ideal start signal for the TOF measurements. A corresponding setup for laser SNMS is schematically shown in **Figure 10**. KrF excimer lasers operating at  $\lambda = 248.6$  nm corresponding to a photon energy of 4.99 eV are frequently employed for pulse widths in the nanosecond-range providing up to several 100 mJ per pulse. For shorter pulse times

**Figure 10** Scheme of a laser SNMS microprobe.

down to a few 100 fs often hybrid excimer – dye laser systems or frequency multiplexed Nd:YAG lasers are used. The latter extend into the VUV-regime with photon energies above 10 eV, which enable single photon ionization (SPI) for almost all elements. In contrast to REMPI, SPI provides another nonselective approach for laser postionization. It was originally elaborated for the detection of desorbed or sputtered organic molecules, but is also employed for inorganic surface analysis.

TOF mass spectrometers of the reflectron type are particularly suitable because they compensate, via different path lengths in an electrostatic reflector, for the time spreading caused by the energy distribution of the sputtered particles. In contrast to quadrupole or magnetic sector mass spectrometers, TOF instruments enable parallel detection of all species in a bunch of postionized sputtered particles. Repetition

frequencies of the postionizing lasers are often in the 10 Hz regime, but extend sometimes to the order of  $10^2$  Hz. Hence, sample bombardment can also be performed in a pulse mode, thus reducing the consumption of sample material in addition to the high particle economy achieved by the parallel detection in a TOF spectrometer. As a characteristic figure,  $\sim 10^{-10}$  g of sample material is consumed for ppm analysis.

Laser SNMS requires the operation with properly selected duty cycles that control the delay times between the primary ion pulse, a pulsed extraction voltage for separating the secondary ions from postionized neutrals, and the firing of the postionizing laser pulse. Such duty cycles have, in addition, to be synchronized with the stepwise motion of the pulsed primary ion beam across the sample surface in the microprobe mode of laser SNMS. The selection of appropriate duration and decay times of the ion and laser pulses, of the laser intensity, and beam shape is important to make the photoion yields independent on the sputtered particle velocities. The detection volume must be matched to the entrance ion optics of the TOF such that it becomes independent of the individual ionization process. Usually, laser intensities in the range from  $10^6$  to  $10^{12}$  W cm $^{-2}$  are applied. While the particle density in the detection volume is monitored at small laser intensities, the particle flux is measured at high photon densities.

An example for surface imaging by laser SNMS is presented in **Figure 11**. The signal of the  $^{64}\text{Ni}$  isotope with an abundance of 1.1% was used to image a Ni grid pressed onto an Ag substrate. **Figure 11** demonstrates a detection power again below  $10^{-2}$  for surface microanalysis with laser SNMS. When an acquisition time of 1 s in the electron gas mode of SNMS is compared with signal collection over 100 laser pulses in the nonresonant photoionization mode, almost identical values of primary ion charge  $\sim 10^{-10}$  C per pixel are necessary for surface imaging with a lateral resolution  $\leq 1 \mu\text{m}$  and a detection power of  $10^{-3}$ – $10^{-2}$ .

## Surface Analysis and Depth Profiling with SNMS

### Quantitative Surface Analysis

The simple and straightforward quantifiability that is expected from the strict separation between particle ejection and ionization and has been demonstrated by many examples is the main justification for any postionization technique employed in the mass spectrometry of solids. The quantification procedure being outlined below has been developed primarily

**Figure 11** Laser SNMS micrograph of a Ni grid (20  $\mu\text{m}$  bars) displaying the  $^{64}\text{Ni}$  signal. Analysis conditions: 25 keV  $\text{Ga}^+$  of 6 nA with 1  $\mu\text{m}$  spot size; nonresonant multiphoton ionization at  $\lambda = 248 \text{ nm}$ . Viewed area  $1 \times 1 \text{ mm}^2$ , imaged with  $128 \times 128$  pixel during 164 s.

for the electron gas version, but applies also to the other SNMS techniques. The basic relation for the SNMS signal  $I(X^0)$  of a neutral species  $X$  being sputter released from the sample is given by

$$I(X^0) = I_p Y_x \alpha_x^0 \eta_x^v (1 - \alpha_x^+ - \alpha_x^-) \quad [2]$$

where  $I_p$  is the bombarding ion current onto the sample and  $\eta_x$  the detection efficiency for a postionized particle  $X^0$ . The quantity carrying the analytical information is the partial sputtering yield  $Y_x$ , which describes the formation probability of a particle  $X$  to be mass analyzed. The postionization probability  $\alpha_x^0$  for  $X$  must be corrected with regard to those particles contributing to  $Y_x$  but being ejected already as positive or negative secondary ions  $X^{+,-}$  with the respective ionization coefficients  $\alpha_x^{+,-}$ . As mentioned earlier, the values of  $\alpha_x^{+,-}$  in the vast majority of all cases are much smaller than unity. Hence, the term in parentheses in eqn [2] can generally be neglected without an appreciable loss in accuracy.

Since the postionization probability  $\alpha_x^0$  of an analyzed species  $X$  is determined by the postionization method and thus becomes a constant of the specific SNMS apparatus, the product  $\alpha_x^0 \cdot \eta_x$  can be combined to one apparatus constant  $D_x$ , which is the detection coefficient for  $X$  in the particular SNMS system. Equation [2] then reads:

$$I(X^0) = I_p Y_x D_x \quad [2a]$$

When the flux of sputtered particles contains only a negligible fraction of molecules, which has been shown to be the case for samples with metallic or covalent bonding, the partial sputtering yield  $Y_x$  under stationary condition is given by

$$Y_x = c_x \cdot Y_{\text{tot}} \quad [3]$$

where  $c_x$  is the atomic concentration of a sample component  $X$  and  $Y_{\text{tot}}$  the total sputtering yield under the respective bombarding conditions. When eqn [2a] is combined with eqn [3], the atomic concentrations of two elements  $i$  and  $j$  are related by

$$\frac{c_i}{c_j} = \frac{I(X_i^0) D_j}{I(X_j^0) D_i} \quad [4]$$

By introducing relative detection factors  $D_i^{\text{rel}}$ , all individual  $D_x$  are referred to the value of  $D_R$  for one identical reference element  $R$ , i.e.,  $D_x^{\text{rel}} = D_x/D_R$ . Since  $\sum c_x = 1$ , the relation

$$c_x = \frac{I(X^0)/D_x^{\text{rel}}}{\sum_i I(X_i^0)/D_i^{\text{rel}}} \quad [5]$$

is easily obtained for the concentration of the atomic constituent  $X$  in the sample.

For the quantification via eqn [5] all SNMS intensities have to be taken from the same SNMS spectrum or measured under identical experimental conditions. The values of  $D_i^{\text{rel}}$  can be easily determined from calibration measurements with standard samples of well-known composition. Since, particularly for low energies of the bombarding primary ions, the energy and angular distributions of the sputtered neutrals can be subjected to non-negligible changes, the absolute detection factors  $D_x$  may too become dependent from the bombarding energy. The relative detection factors  $D_i^{\text{rel}}$  will be less affected by such influences, especially for an oblique take-off angle as discussed earlier.

In Figure 12, the SNMS intensities taken directly from the mass spectra obtained with electron gas SNMS for different standard samples with specified compositions are plotted versus the concentrations  $c_x$  of the sample constituents. It can be seen that the relative detection factors for electron gas SNMS vary only little for a large variety of elements. Figure 12 demonstrates that the SNMS signals obtained with the electron gas method describe the sample composition within a factor of  $\sim 2$  without any further evaluation procedure being employed. Such a simple and very convenient behavior can be well understood from eqn [1] since the integral for  $\alpha_x^0$  is not much sensitive to the variations of the individual functions referring to an analyzed species  $X$ . This will be

**Figure 12** SNMS signals of various elements in three different standards vs. their specified concentrations.

different for electron beam SNMS where  $\alpha_x^0$  depends on the position of the electron beam energy along the ionization function  $Q_x$  of a species  $X$ . Large differences between individual detection factors occur for laser SNMS, particularly when near-resonance conditions for photon absorption are met for certain species  $X$ . For the same reason the detection coefficients in laser SNMS vary also with the photon energy. Different variations of the photoionization probability with the applied laser power (see Figure 13) as discussed earlier are still an obstacle for the quantification of laser SNMS, when saturation of the postionization process for all species  $X$  is not achieved.

The small variations of the relative detection factors in electron gas SNMS for the different species  $X$  can be reduced significantly by putting

$$D_x \sim A_x^{1/2} / U_x^{\text{ions}} \quad [6]$$

where  $A_x$  is the atomic mass number and  $U_x^{\text{ions}}$  the ionization potential of  $X$ . Equation [6] results readily from plausibility arguments on the individual dwelling times in the postionizing volume and the postionization probabilities for different species  $X$ . A much higher precision, however, is obtained with the evaluation procedure from eqn [5] when employing the exact relative detection factors for the respective SNMS instrument. An example is given in Figure 14, where for an unknown multielement sample the concentrations  $c_x$  obtained using eqn [5] from the corresponding SNMS spectrum are compared with the results from conventional analysis by wet chemistry.

The basic eqn [2] is also valid for neutral sputtered molecules. In that case the influence of electron impact dissociation can be included in the respective detection factors  $D_x$  for a molecular species  $X$ . As an

**Figure 13** Various photoion signals vs. laser intensity in non-resonant multiphoton ionization with a KrF excimer laser ( $\lambda = 248$  nm). (By S. Kaesdorf, H. Schröder and K.L. Kompa.)

**Figure 15** Correlation plot for atomic surface oxygen concentrations on polycrystalline Ta determined by SNMS and by *in situ* Auger electron spectroscopy AES.

**Figure 14** Correlation plot for the atomic concentrations in a metal sample determined by SNMS and conventional analysis by wet chemistry.

example for such species, diatomic oxide molecules like TaO with strong ionic bonds are sputter-generated via the so-called direct emission process. For a binary sample like an oxide or a hydride the formation probability for a sputtered molecule  $MB$  and, hence, the respective SNMS signal  $I(MB^0)$  are predicted to pass through a maximum for equal surface concentrations of  $c_B^S = c_M^S = 0.5$ .  $B$  refers to the

lighter and  $M$  to the heavier component, e.g., to oxygen and a metal or hydrogen and silicon. From the respective formation mechanism the relation

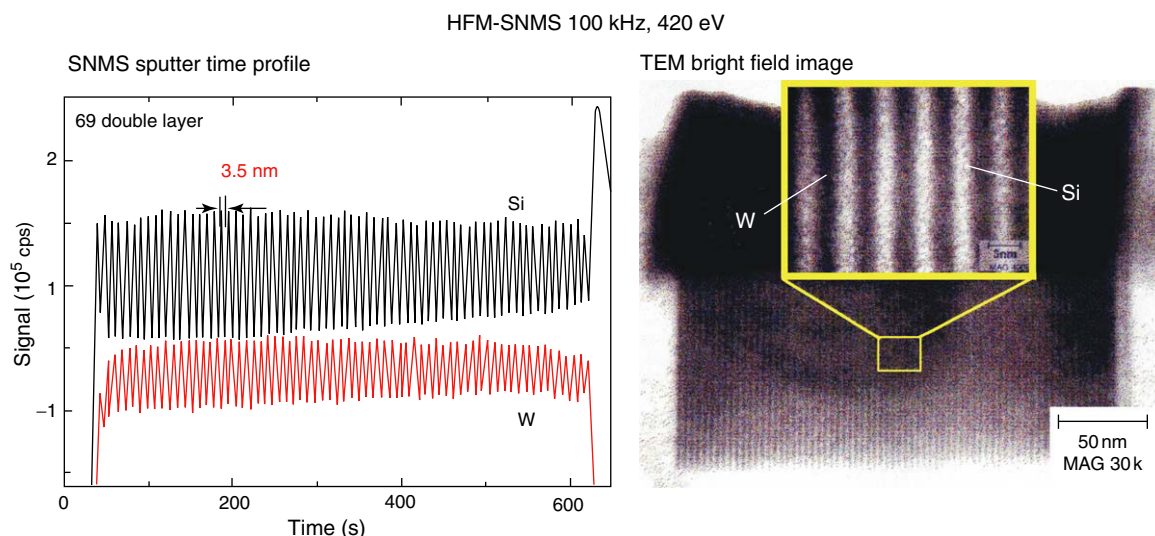

$$c_B^S = 0.5 \left[ \left\{ 1 - \frac{I(MB^0)}{I_{\max}(MB^0)} \right\}^{0.5} \right] \quad [7]$$

is readily derived for the actual surface concentration  $c_B^S$ .  $I_{\max}(MB^0)$  is the maximum SNMS signal for  $MB$  referring to  $c_B^S = 0.5$ .

A correlation plot for the  $c_0^S$  values derived from the variation of  $I(\text{TaO}^0)$  from an oxygen covered Ta surface via eqn [7] is shown in **Figure 15** where the SNMS results are compared with the respective oxygen surface concentration being determined *in situ* by AES. The convincing agreement between both sets of results for  $c_0^S$  proves simultaneously the direct emission model for molecular sputtering leading to eqn [7]. More important, eqn [7] makes SNMS to a self-calibrating surface analytical technique without the necessity of external standards when the conditions for the maximum formation probability of  $MB$  molecules, i.e., at  $c_B^S = c_M^S = 0.5$  for a binary system, are passed through during the analysis.

### High-Resolution Depth Profiling

The very favorable features of electron gas SNMS for high-resolution depth profiling being achieved with the DBM technique (see above) become exemplified by **Figure 16**. This figure shows the depth profile through a W-Si multilayer stack on a ceramic

**Figure 16** SNMS analysis of a W-Si multilayer structure. A cross-sectional TEM image of the layer stack is included (IFOS GmbH Kaiserslautern).

support. Profiling was performed with the high-frequency mode on SNMS (see above) using a rectangular high-frequency voltage of 100 kHz with a full amplitude of 420 V. For a double-layer thickness of only 3.6 nm the individual W- and Si-sublayers consisting of 7–8 atomic layers each become well resolved down to the substrate. The measured interface widths between the sublayers amount to 3–4 atomic distances and correspond well with the previously mentioned physical limitations for the depth resolution during sputter removal. For comparison a TEM image of a cross-section through the layer stack is added in **Figure 16**.

Depth profile analysis with SNMS also provides the possibility of determining the absolute depth scale quantitatively from the variation of the SNMS signals themselves. The respective evaluation procedure is based on the characteristic property of SNMS that all sputter-removed particles are collected with individual but constant factors when sputter profiling through a layer structure of varying composition.

The time-dependent sputter eroded depth  $z$  is given by

$$z(t) = \int_0^t j_p \frac{Y_{\text{tot}}(t')}{n(t')} dt' \quad [8]$$

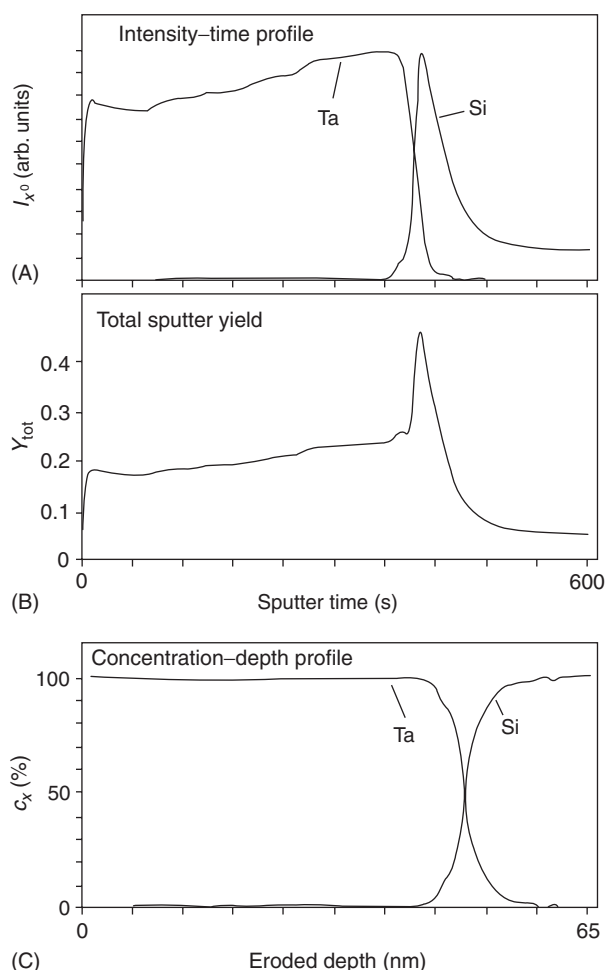

where  $j_p$  is the bombarding ion current density employed for the sputter removal and  $n$  is the time- (or depth-) dependent particle density in the sample. The time-dependent total sputtering yield  $Y_{\text{tot}}$  can be readily determined by adding all partial sputtering yields  $Y_x$ . These quantities are directly related with the time-dependent individual SNMS signals via eqn

[2a]. Finally, the time-dependent sample density can be approached by

$$n(t) = \sum_x c_x(t) n_x \quad [9]$$

where the  $c_x(t)$  are derived from the SNMS signals according to eqn [5]. As the only approximation entering the depth calibration procedure, the densities  $n_x$  are replaced by the respective bulk densities of the elemental bulk material X. By inserting  $Y_{\text{tot}}(t)$  and  $n(t)$  into eqn [8], the eroded depth  $z$  for a certain sputtering time is exclusively obtained from the time-dependent SNMS signals  $I(X^0, t)$ .

As an instructive example the results from sputter depth-profiling through a sputter-deposited Ta layer on a Si(100) substrate are shown in **Figure 17**. If literature values for the sputtering yields of Ta and Si are used to convert the sputter-time axis into a depth scale, a 84–16% interface width of 2.1 nm is obtained from the intensity-sputter time profile in **Figure 17**. However, the actual time- (or depth-) dependent total sputtering yield  $T_{\text{tot}}(t)$ , determined from the SNMS signals via eqn [2a] with  $D_{\text{Ta}} = D_{\text{Si}}$  as a good approximation, is found to vary with the sputter time as shown in **Figure 17B** with a peak at the interface region. The subsequent evaluation according to eqn [8] gives the true concentration-depth profile with a 84–16% interface width of 3.6 nm (**Figure 17C**). Hence, interface widths that are determined from sputter-time profiles employing surface analytical techniques become questionable in general, if time- or depth-dependent variations of the total sputtering yield (or the removal velocity) are not carefully taken into account. The obtained mean

**Figure 17** SNMS depth profiling of a sputter deposited Ta layer on Si(1 0 0) with 250 eV Ar<sup>+</sup> ions at 1 mA cm<sup>-2</sup>.

thickness of the Ta layer of 48 nm agrees with that expected from the deposition procedure and was independently confirmed through measurements with a step profilometer. The behavior of the SNMS signal, which is determined by the actual sputtering yield, points to structural inhomogeneities across the Ta film.

As with all mass spectrometric techniques, SNMS can be employed for isotope analysis, and is, in contrast to Auger electron spectroscopy, not restricted to elements with atomic numbers  $\geq 3$ . For example, quantitative analysis of the hydrogen content in a sample can – apart from the evaluation of the H-signal itself – be achieved from the ratio of the SNMS signals of the hydride molecule and the respective hydride forming element. According to the direct emission model for the generation of sputtered molecules as mentioned earlier, this ratio is directly proportional to  $c_H$ . An example is presented in **Figure 18** for the depth-dependent hydrogen concentration in a

**Figure 18** Hydrogen depth profile measured with SNMS in an amorphous hydrogenated Si layer with a P-doped n-layer on top. Curve 'theoretical' depicts the H-profile expected from the partial pressure variations during the sputter deposition process.

hydrogenated amorphous silicon structure that was deposited under varying partial hydrogen pressure  $p(\text{H}_2)$ . The solid line in **Figure 18** represents the hydrogen profile that is expected from the variation of  $p(\text{H}_2)$  during deposition. As a detail the P-concentration in a phosphorous-doped layer on top of this structure as determined from the respective electron gas SNMS measurements is included.

### Introduction

Laser ionization of atomic or molecular neutrals in the gas phase offers an unsurpassed potential with respect to analytical specificity and sensitivity. Unlike other ionization methods, photon absorption imparts to the analyte a well-defined amount of energy. Addressing the transitions between specific energy levels allows one species in a complex environment to be analyzed with isotopic selectivity. Because lasers deliver sufficiently high fluxes to saturate the population of an excited state, virtually each neutral in the irradiated volume is ionized. Hence, the ionization efficiency,  $\sim 1$ , exceeds that of current methods by a factor of  $10^2$ – $10^4$ .

Sputtered neutrals mass spectrometry (SNMS) involves the measurement of the postionized neutrals, generated either on a macroscopic scale (e.g., atomization in a graphite furnace) or from a microscopic volume of a solid (e.g., by focused primary ion or laser beam). In comparison to current ionization methods in SNMS, e.g., electron and low-pressure plasma ionization, lasers allow sensitivity and specificity of the postionization step to be ultimately optimized. Surface analysis requires the initial neutrals to be generated exclusively from the upper few monolayers of a solid, preferentially with a lateral resolution in the micrometer range. Essentially, two methods exist. Laser microbeam irradiation evaporates neutrals from the upper 10–100 nm of a solid with a diffraction-limited lateral resolution (spot diameter of  $0.5\ \mu\text{m}$  at a wavelength ( $\lambda$ ) of 250 nm). Alternatively, bombardment of the solid with a limited dose ( $< 10^{12}\ \text{ions cm}^{-2}$ ) of primary ions with energy in the kiloelectronvolt range generates neutrals from only the upper (few) monolayers over a surface area of up to  $250\ \mu\text{m} \times 250\ \mu\text{m}$  (size depends on sputter and ionization yield). The monolayer erosion makes primary ion bombardment the

method of choice for ‘surface analysis by laser ionization’ (SALI).

Lasers and primary ion beams bring sufficient energy into the sample to break even the strongest bond in a molecule. In spite of the resulting atomization, the ultrafast energy deposition and desorption processes still allow a significant fraction of (even thermolabile) analytes to be released in the form of intact molecules. Hence, SALI can address elemental as well as molecular (and organic) analysis.

From the 1980s onwards, dedicated setups (and acronyms) have been developed, e.g., SALI (Becker and Gillen, 1984), sputter initiated resonance ionization spectrometry (SIRIS) (Parks, 1990), surface analysis by resonant ionization of sputtered atoms (SARISA, Pellin *et al.*, 1989), and the Chicago–Argonne resonance ionization mass analysis (CHARISMA, Ma *et al.*, 1995). The recent proliferation of commercial time-of-flight (TOF) secondary ion mass spectrometry (SIMS) instruments stimulates their conversion into SALI setups.

### Fundamentals

#### Postionization SNMS versus SIMS

When an atomic primary ion of 10–25 keV impacts on a solid, it penetrates into the sample over a distance of typically 10–50 nm and dissipates its energy by inelastic collisions with the sample atoms along its trajectory. The resulting displacement of atoms and destruction of the molecular structure start a complex series of electronic, vibrational, and ultrafast thermal processes that finally cause electrons, atoms, and intact molecules, radicals, and secondary ions to be set free from the upper monolayer(s). Depending on the composition of the analyte and matrix, the ratio  $I_{\text{SIMS}}$  of directly emitted secondary ions over neutrals may range from  $10^{-2}$  to  $10^{-6}$ . These large differences in  $I_{\text{SIMS}}$  and detection sensitivity severely hamper the application of SIMS for survey analysis. In contrast, the relative abundance of sputtered neutrals remains relatively constant (i.e., 99 and 99.9999% for  $I_{\text{SIMS}}$  of  $10^{-2}$  and  $10^{-6}$ , respectively). On the condition that the gas-phase ionization step

### Introduction

Laser ionization of atomic or molecular neutrals in the gas phase offers an unsurpassed potential with respect to analytical specificity and sensitivity. Unlike other ionization methods, photon absorption imparts to the analyte a well-defined amount of energy. Addressing the transitions between specific energy levels allows one species in a complex environment to be analyzed with isotopic selectivity. Because lasers deliver sufficiently high fluxes to saturate the population of an excited state, virtually each neutral in the irradiated volume is ionized. Hence, the ionization efficiency,  $\sim 1$ , exceeds that of current methods by a factor of  $10^2$ – $10^4$ .

Sputtered neutrals mass spectrometry (SNMS) involves the measurement of the postionized neutrals, generated either on a macroscopic scale (e.g., atomization in a graphite furnace) or from a microscopic volume of a solid (e.g., by focused primary ion or laser beam). In comparison to current ionization methods in SNMS, e.g., electron and low-pressure plasma ionization, lasers allow sensitivity and specificity of the postionization step to be ultimately optimized. Surface analysis requires the initial neutrals to be generated exclusively from the upper few monolayers of a solid, preferentially with a lateral resolution in the micrometer range. Essentially, two methods exist. Laser microbeam irradiation evaporates neutrals from the upper 10–100 nm of a solid with a diffraction-limited lateral resolution (spot diameter of  $0.5\ \mu\text{m}$  at a wavelength ( $\lambda$ ) of 250 nm). Alternatively, bombardment of the solid with a limited dose ( $< 10^{12}\ \text{ions cm}^{-2}$ ) of primary ions with energy in the kiloelectronvolt range generates neutrals from only the upper (few) monolayers over a surface area of up to  $250\ \mu\text{m} \times 250\ \mu\text{m}$  (size depends on sputter and ionization yield). The monolayer erosion makes primary ion bombardment the

method of choice for ‘surface analysis by laser ionization’ (SALI).

Lasers and primary ion beams bring sufficient energy into the sample to break even the strongest bond in a molecule. In spite of the resulting atomization, the ultrafast energy deposition and desorption processes still allow a significant fraction of (even thermolabile) analytes to be released in the form of intact molecules. Hence, SALI can address elemental as well as molecular (and organic) analysis.

From the 1980s onwards, dedicated setups (and acronyms) have been developed, e.g., SALI (Becker and Gillen, 1984), sputter initiated resonance ionization spectrometry (SIRIS) (Parks, 1990), surface analysis by resonant ionization of sputtered atoms (SARISA, Pellin *et al.*, 1989), and the Chicago–Argonne resonance ionization mass analysis (CHARISMA, Ma *et al.*, 1995). The recent proliferation of commercial time-of-flight (TOF) secondary ion mass spectrometry (SIMS) instruments stimulates their conversion into SALI setups.

### Fundamentals

#### Postionization SNMS versus SIMS

When an atomic primary ion of 10–25 keV impacts on a solid, it penetrates into the sample over a distance of typically 10–50 nm and dissipates its energy by inelastic collisions with the sample atoms along its trajectory. The resulting displacement of atoms and destruction of the molecular structure start a complex series of electronic, vibrational, and ultrafast thermal processes that finally cause electrons, atoms, and intact molecules, radicals, and secondary ions to be set free from the upper monolayer(s). Depending on the composition of the analyte and matrix, the ratio  $I_{\text{SIMS}}$  of directly emitted secondary ions over neutrals may range from  $10^{-2}$  to  $10^{-6}$ . These large differences in  $I_{\text{SIMS}}$  and detection sensitivity severely hamper the application of SIMS for survey analysis. In contrast, the relative abundance of sputtered neutrals remains relatively constant (i.e., 99 and 99.9999% for  $I_{\text{SIMS}}$  of  $10^{-2}$  and  $10^{-6}$ , respectively). On the condition that the gas-phase ionization step

features a uniform yield for all analytes, the ion intensities in SALI directly reflect the composition of the sputtered cloud, which in turn corresponds to the sample composition (unless selective sputtering occurs). Moreover, postionization under vacuum conditions avoids the matrix effects that result from interspecies interactions during the one-step sputtering ionization in SIMS.

The basic design of a typical postlaser ionization SNMS instrument in **Figure 1** resembles that of a TOF SIMS setup except for the laser beam, which is aligned parallel to the sample at a distance of 1–3 mm to the surface. The beam diameter is typically 1 mm. Pulsed biasing of the sample holder and ion extraction electrode potential prevents directly emitted secondary ions and electrons to enter the mass spectrometer. The laser is fired when the optimal density of neutrals in the irradiated volume is reached.

The number of parent ions ( $N_d$ ), detected from the upper monolayer when  $1\text{ mm}^2$  of sample is bombarded with  $N_{pi}$  primary projectiles, can be estimated by factorizing the following contributions:

$$N_d = N_s \times N_{pi} \times S \times G(\theta) \times D(E_{kin}, \Delta E_{kin}, \Delta t_p) \times I(N_\phi, \sigma) \times F(E_{exc}) \times T(MS, m/z, t, \dots) \quad [1]$$

where  $N_s$  = number of analyte molecules or atoms in  $1\text{ mm}^2$  of a monolayer.

$S$  = number of analyte neutrals sputtered by one primary ion.

$G(\theta)$  = geometry factor, i.e., fraction of  $S$  that is emitted with an angle within the solid angle of the ionization volume (seen from the sample surface).

**Figure 1** Schematic diagram of the basic SALI experiment (see text for details).

$D(E_{kin}, \Delta E_{kin}, \Delta t_p)$  = delay efficiency, i.e., fraction of  $S$  that is present in the ionization volume when the laser is 'fired'. The delay between the primary ion and laser pulse must account for the kinetic energy ( $E_{kin}$ ) of the neutrals (time needed to reach the ionization volume). The spread on  $E_{kin}$  and the duration of the primary ion pulse (or delayed release of neutrals) can reduce  $D$  significantly.

$I(N_\phi, \sigma)$  = yield of laser postionization, i.e., number of ions produced over number of neutrals present in the ionization volume. The yield can be expressed in terms of the cross-section for photon absorption  $\sigma$  (function of the analyte and photon energy  $E_\phi$ ) and the number of photons  $N_\phi$  in the ionization volume during the entire pulse.

$F(E_{int})$  = fragmentation factor ( $\leq 1$ ) taking into account that some parents are detected as daughter ions at a different  $m/z$ . Atomic ions are a favorable case with  $F = 1$  but in particular (polar) organic analytes readily undergo fragmentation depending on the internal stress  $E_{int}$ , i.e. (in a first approximation) the energy difference between the absorbed photons and ionization potential (IP).

$T(MS, m/z, t, \dots)$  = transmission and detection efficiency ( $\leq 1$ ), i.e., ratio of ions detected over those generated in the ionization volume. The factor depends on the instrumental optimization of ion extraction, transmission, and detector efficiency.

Introduction of realistic estimates for the different factors in eqn [1] evidences the potential advantage of laser postionization TOF-SNMS relative to TOF-SIMS. For instance, the upper monolayer of a copper target contains  $2.2 \times 10^{13}$  atoms  $\text{mm}^{-2}$ . Use of a 10 ns pulse from a primary ion beam ( $1\text{ }\mu\text{A mm}^{-2}$ ) gives  $N_{pi} = 6.24 \times 10^4$  projectiles per bombardment event. In a first approximation, each primary ion can be assumed to sputter constituents from a surface area with a diameter of 10 nm and a monolayer thickness. This volume contains  $1.7 \times 10^3$  Cu atoms. Postionization of Cu atoms with ArF or KrF excimer lasers can achieve complete ionization ( $I(N_\phi, \sigma_A) = 1$ ) while  $F = 1$  for atomic ions to stay on the safe side. The assumption of a laser beam with diameter of 1 mm at a distance of 3 mm to the surface allows a value of  $3.8 \times 10^{-2}$  to be calculated for  $G(\theta)$ .

The factor  $D$  is more difficult to derive. Sputtered Cu atoms ejected with a mean  $E_{kin}$  of  $\sim 3\text{ eV}$  have a velocity of  $3 \times 10^3\text{ ms}^{-1}$ . The time needed to reach and traverse the ionization volume is  $\sim 1$  and  $0.33\text{ }\mu\text{s}$ , respectively. Accounting for the emission angle and velocity distributions of the sputtered

neutrals,  $\sim 15\%$  of the Cu neutrals are within the ionization volume when a 10 ns laser pulse is fired at  $\sim 1.5 \mu\text{s}$  after the primary ion pulse. State-of-the-art instruments allow a combined efficiency  $T$  for ion extraction, transmission, and detection as high as 30% to be achieved.

Substituting the values in eqn [1] gives the number of ions, detected in laser TOF SNMS per primary ion pulse from  $1 \text{ mm}^2$  of copper:

$$\begin{aligned} N_d(\text{SNMS}) &= (1.7 \times 10^3) \times (6.24 \times 10^4) \times (6) \\ &\quad \times (3.8 \times 10^{-2}) \times (0.15) \times (1) \times (0.3) \\ &= 1.1 \times 10^6 \end{aligned} \quad [2]$$

The corresponding figure for the directly emitted secondary  $\text{Cu}^+$  ions in SIMS (without laser postionization) can be estimated using eqn [1] without the factors  $G$  and  $D$ . The ionization yield  $I_{\text{SIMS}}$  is  $10^{-4}$  under the specified conditions while the specific ion properties (emission angle and velocity distributions, mean  $E_{\text{kin}}$  and  $\Delta E_{\text{kin}}$ ) reduces  $T$  to 0.1. This gives:

$$N_d(\text{SIMS}) = N_s \times N_{\text{pi}} \times S \times I_{\text{SIMS}} \times F \times T \quad [3]$$

$$\begin{aligned} N_d(\text{SIMS}) &= (1.7 \times 10^3) \times (6.24 \times 10^4) \times (6) \\ &\quad \times (10^{-4}) \times (1) \times (0.1) = 6.4 \times 10^3 \end{aligned} \quad [4]$$

Otherwise stated, the detected number of  $\text{Cu}^+$  ions from a given primary ion pulse is  $\sim 200$  times higher in laser postionization SNMS than in SIMS. The situation becomes different for analytes with high  $I_{\text{SIMS}}$ . For instance, the  $I_{\text{SIMS}}$  of  $\text{Al}^+$  from aluminum targets is  $\sim 1.25 \times 10^{-2}$ , and thereby virtually annihilating the advantage of SNMS with respect to sensitivity. The reduction of matrix effects remains an advantage of SNMS.

### Laser Ionization Schemes

Photon absorption is by far the most elegant way to give neutrals a well-defined amount of energy, which is almost exclusively converted into electronic excitation.

Single photon ionization (SPI) requires  $E_\phi > \text{IP}$  (see Figure 2) with  $E_\phi$  given by

$$E_\phi = hc/\lambda \quad [5]$$

where  $h$  is Plank's constant and  $c$  the speed of light.

Modern lasers provide monochromatic beams in the UV and VUV range down to  $\sim 200 \text{ nm}$  ( $\text{IP} < 6 \text{ eV}$ ) while the excimer line of  $157 \text{ nm}$  allows transitions of  $7.9 \text{ eV}$  to be addressed. The overall ionization efficiency for elemental species primarily depends on the absorption probability, which is in turn a

**Figure 2** Survey of laser ionization schemes for gas-phase analytes: single photon ionization (SPI), multiphoton ionization (MPI) with distinction between resonant ionization (RI), resonance enhanced multiphoton ionization (REMPI), and nonresonant multiphoton ionization (NRMPI). Real and virtual states are denoted by R and S, respectively, while C refers to the ionization continuum.

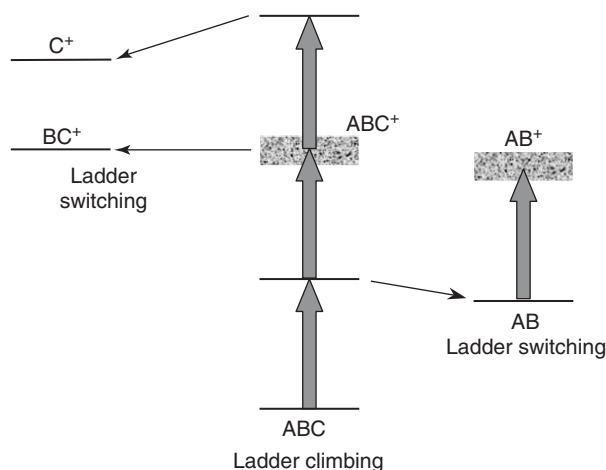

function of the density of the neutrals and the photon flux (intensity) in the ionization volume. Current lasers provide sufficient intensity to ionize nearly all atoms in the ionization volume. The situation is different for molecular species. As only little  $E_{\text{kin}}$  is given to the departing photoelectron, parent ions  $\text{M}^{+\bullet}$  obtain an amount of internal energy  $E_{\text{int}}$  corresponding to  $(E_\phi - \text{IP})$ . Unlike ionized atoms,  $\text{M}^{+\bullet}$  tend to relax their internal stress by fragmentation. Depending on the  $\lambda$ , the ratio of daughter ions over parent can be tuned for maximal yield of either  $\text{M}^{+\bullet}$  or fragment ions to obtain molecular weight or structural information, respectively. Unfortunately, each daughter costs the life of her parent and generation of fragments lowers the signal intensity of  $\text{M}^{+\bullet}$ .

Strictly speaking, distinction must be made between resonant and nonresonant SPI. In the resonant case, the  $E_\phi$  exactly matches the transition from the ground state into an autoionizing bond state above the IP. As a result, the high  $\sigma$  allows complete ionization to be achieved with lower laser intensities than when nonresonant SPI is used. In the latter case, the  $E_\phi$  drives the analyte 'somewhere' into the continuum above the IP.

Analytes with  $\text{IP} > 8 \text{ eV}$  require multiphoton ionization (MPI), i.e., consecutive absorption of two or more photons. A first photon transfers the analyte into a specific, electronically excited state and subsequent uptake of photon(s) is required to overcome the IP. The efficiency of this sequential process depends on the decay rate of the intermediate state relative to the photon flux density that promotes its population. The balance between the two competitive effects can be quantified by a quality factor as in

electric resonance circuits. The ultimate efficiency is obtained in resonant (R) MPI, often denoted as resonant ionization (RI). In this case, the  $E_\phi$  of the photons used exactly corresponds to the energy gaps between the ground level and the long-lived excited state on the one hand, and between that excited state and an autoionizing level on the other. Selectivity is optimized when molecules have low internal excitation. For instance, jet cooling of the gas-phase analytes reduces the population of vibrational states and the  $\sigma$  shows sharp maxima as a function of  $\lambda$ . Even isotope-labeled molecules can be discriminated from unlabelled ones. However, the situation is less ideal for the ion-beam sputtered neutrals because of their vibrational excitation. Therefore, resonance enhanced (RE) MPI is preferred in SALI.

Use of photons with a  $\lambda$  that does not match the transition to a long-lived intermediate state, allows nonresonant (NR) MPI to be performed by the 'quasisimultaneous' absorption of two or more photons. The sensitivity and selectivity of NRMPI is much lower than that of REMPI. The photon flux density (intensity) becomes a prime factor in NRMPI. Using laser pulses with a duration of  $<10$  ns and peak power densities above  $10^{10}$  and  $10^{13}$  W cm $^{-2}$  are required for NRMPI involving two and more photons, respectively. In the case of three-photon MPI of molecules, further increase of the flux density does not really improve the yield as a result of the so-called 'ladder mechanism'. Above a given threshold, the laser intensity primarily determines the extent of fragmentation. **Figure 3** illustrates the ladder concept

**Figure 3** The effects of fragmentation and ladder switching in the MPI process of a molecule ABC at high photon fluxes. (Reprinted from Vorsa V, Kono T, Willey KF, and Winograd N (1999) Femtosecond photoionisation of ion beam desorbed aliphatic and aromatic amino acids: fragmentation via  $\alpha$ -cleavage reactions. *Journal of Physical Chemistry B* 103: 7889–7895; © American Chemical Society.)

for a neutral ABC of which the ionization requires isoenergetic photons. The first photon brings ABC one step higher on its ladder, where competition occurs between uptake of another photon (ladder climbing, requires high flux density) or fragmentation into AB and C (ladder switching). In the latter case, the fragments AB and C can start their own process of ladder climbing. When a second photon brings the already excited ABC neutrals above the IP, fragmentation into, e.g.,  $BC^+$  competes with absorption of an additional photon yielding an excited state of  $ABC^{+\bullet}$ . The ladder concept explains the breakdown of stable molecules, such as benzene, into graphite-like  $C_n^+$  ions using photons of 4.8 eV.

Ladder switching in organic molecules often involves processes of internal conversion (IC) and intersystem crossing (ISC), which bring molecules in vibrationally excited states and favor their fragmentation. As the rate constant of IC and ISC is typically  $<10^6$  and  $10^{11}$  s $^{-1}$ , respectively, use of lasers with a pulse duration in the femtosecond range makes excitation faster than the depopulation of the excited state and increases the yield of  $M^{+\bullet}$ . The growing availability of the tabletop ultrafast laser systems brings a tremendous potential for the ionization of large fragile organic molecules within the reach of the analytical chemist.

## Instrumentation

A TOF-mass analyzer is by far the instrument of choice for SALI applications. **Figure 4** illustrates the mass separation process. Electrostatic acceleration is the simplest way to distinguish between ions of different  $m/z$  in a given bunch. A potential difference  $V$  (typically 3 kV) between the sample and extraction electrode (on a distance of  $\sim 2$  mm) gives all ions the same  $E_{\text{kin}}$  and, hence, an  $m/z$ -dependent velocity  $v$ :

$$\frac{mv^2}{2} = zeV \Rightarrow v = \sqrt{2eV} \sqrt{\frac{z}{m}} \quad [6]$$

The obvious way to measure  $v$  consists in monitoring the time needed to travel a given distance in a field-free region. Hence, the accelerated ion bunch is sent through a tube of 1–2 m (kept on acceleration potential). After some time, the low  $m/z$  ions travel in front of the high  $m/z$  ions. The detector (channel plate with electron multiplier, pulse counting, and time-to-digital conversion) registers the arrival of ions as a function of time. Reference compounds are used to calibrate the time scale as a function of  $m/z$ . A basic requirement is that all ions start their travel in the field-free region at the same time, i.e., typically within 1–10 ns. Since the initial  $E_{\text{kin}}$  of the neutrals

**Figure 4** Schematic diagram of a typical SALI instrument with TOF mass analyzer.

before the ionization is kept during acceleration, the ions of the same  $m/z$  exhibit after acceleration a given  $\Delta E_{\text{kin}}$  and thereby  $\Delta v$ , which broadens the mass spectral peakwidth. Therefore, the ion reflector produces a retarding field aligned under a small angle with the first and second drift tubes. Ions of a given  $m/z$  with a higher  $E_{\text{kin}}$  penetrate deeper into the retarding field and spend more time on the longer path than the ions with lower  $E_{\text{kin}}$ . Adjustment of the retarding field allows, in principle, low and high  $E_{\text{kin}}$  ions of the same  $m/z$  to arrive at the same moment on the detector. The width of the mass spectral peak is reduced and the mass resolution improved without sacrificing sensitivity.

A TOF-MS provides several analytical advantages in comparison to magnetic sector, quadrupole, and ion trap analyzers. An ion beam is readily collimated to the diameter of the detector, allowing high transmission to be achieved. Because no fields have to be scanned, full mass spectra are recorded from each ion bunch. The efficiency, expressed as the ratio of number of ions used for mass analysis over the number of ions to be produced in the source, is high in the case of pulsed ionization. While mass separation requires ions to be introduced in the drift tube during only 1–10 ns, the mass analysis itself takes 100–500  $\mu\text{s}$ . Therefore, a pulsed primary ion gun is turned on during 1–10 ns and turned off during mass analysis. As a result, no sample is wasted. The  $m/z$  range in TOF-MS is only limited by the mass resolution of typically 1000–3000 (10% valley criterion) when ionization pulses of 1–10 ns are applied.

Currently used primary ions are  $\text{Ar}^+$ , produced by electron ionization (EI) of Ar, or  $\text{Ga}^+$ , generated by a liquid metal ion gun (LMIG). Typical beam spot diameters on the sample are 10–25  $\mu\text{m}$  and 50–100 nm

for the EI source and LMIG, respectively. The primary ion energy ranges from 5 to 25 keV. The beam is pulsed by electrostatic bunching. An incidence angle of  $\sim 45^\circ$  with the normal on the sample optimizes the sputtering yield. The release of many secondary electrons alters the surface potential of nonconducting samples and thereby the extraction field. Electron flooding, a conductive coating or mask on the sample, partly solves the problem. Pulsing the voltages on the sample holder and extraction optics keeps directly emitted secondary electrons and ions out of the analyzer.

Alignment of the postionizing laser as close as possible to the sample surface improves  $G(\theta)$ . Depending on the selected ionization scheme, irradiation is achieved with one or more lasers simultaneously. The delay between the primary ion and laser pulses must match the time needed for the neutrals to reach the ionization volume. Hence, adjustment of this parameter is critical to maximize the density of neutrals in the ionization volume. The laser pulse duration of typically 1–20 ns is selected to optimize both ionization probability and mass resolution. The spread on velocity and direction of the neutrals motivates application of relatively long pulses. As a result, the mass resolution in SALI experiments is lower than that for the SIMS mode with the same TOF instrument.

A vacuum of at least  $10^{-8}$  Torr is needed to avoid deposition of contaminants on the sample. Specifically, it takes only 1 s at a pressure of  $10^{-6}$  Torr for a residual vacuum component with sticking coefficient of 1 to form a complete monolayer on the surface.

Apart from the Perkin–Elmer SALI Model 7000, most instruments were developed in house. While the original SALI setup of Becker and Gillen (1984) used

an ion reflector, the SIRIS instrument of Atom Sciences (Oak Ridge, Tennessee) used a linear geometry. The Nd:YAG pumped tunable dye laser and/or mixing with the YAG fundamentals allowed photons with  $\lambda$  between 220 and 570 nm to be used. Isotope selectivity was not possible because the laser bandwidth exceeded the natural linewidth of the atoms. No ion reflector was needed because the RI avoided generation of isobars. The sensitivity for elements was in the low nanogram per gram range. The SARISA instrument built at the Argonne National Laboratories generated neutrals with a 3.5 keV  $\text{Ar}^+$  primary ion beam, focused to a spot with diameter of 250  $\mu\text{m}$ . In contrast to most setups, the primary ion beam impinged perpendicularly on the sample using ingenious ion optics that allowed photoionized neutrals to be extracted along the same axis. A so-called 'energy and angle refocusing' TOF system with two spherical analyzers optimized both mass resolution and acceptance of ions with different  $E_{\text{kin}}$  and emission angles. Elimination of the interference from  $^{56}\text{Fe}^+$  and  $^{28}\text{Si}_2^+$  by the RI scheme yielded a detection limit of 2 ng per g for Fe in Si, which is a demanding key analysis in semiconductor applications. The collaboration between the Chicago University and the Argonne National Laboratories yielded the beautiful acronym 'CHARISMA' for an instrument with elaborated laser optics permitting SALI and laser microprobe mass spectrometry (LMMS) with laser postionization to be compared directly. Primary ion bombardment was achieved either by 5 keV  $\text{Ar}^+$  or  $\text{Ga}^+$  from an LMIG with spot diameters of 500 and 0.1–1  $\mu\text{m}$ , respectively, while a Schwarzschild microscope was used to focus the laser on the sample in the LMMS mode. In both cases, the postionizing laser beam with a diameter of 100  $\mu\text{m}$  was aligned on a distance of only 0.2–0.5 mm above the sample. An in house developed laser system produced pulses as short as 100 fs at  $\lambda = 248$  nm for ultrafast MPI.

## Applications

Virtual absence of commercial instruments makes SALI a niche technique, particularly appreciated in areas where other methods fail. Specifically for elemental analysis, the use of SALI instead of the experimentally more simple and less expensive (S-)SIMS method is motivated by:

- The superior sensitivity for elements with low  $I_{\text{SIMS}}$ .
- The relatively uniform ionization yield for most elements (unlike SIMS) when the population of excited states is driven into saturation under NR

conditions. Unless preferential sputtering occurs, relative peak intensities of the atomic ions in SALI reflect directly the stoichiometry of the sample. This quick 'look and see' analysis is a valuable asset in any analytical strategy.

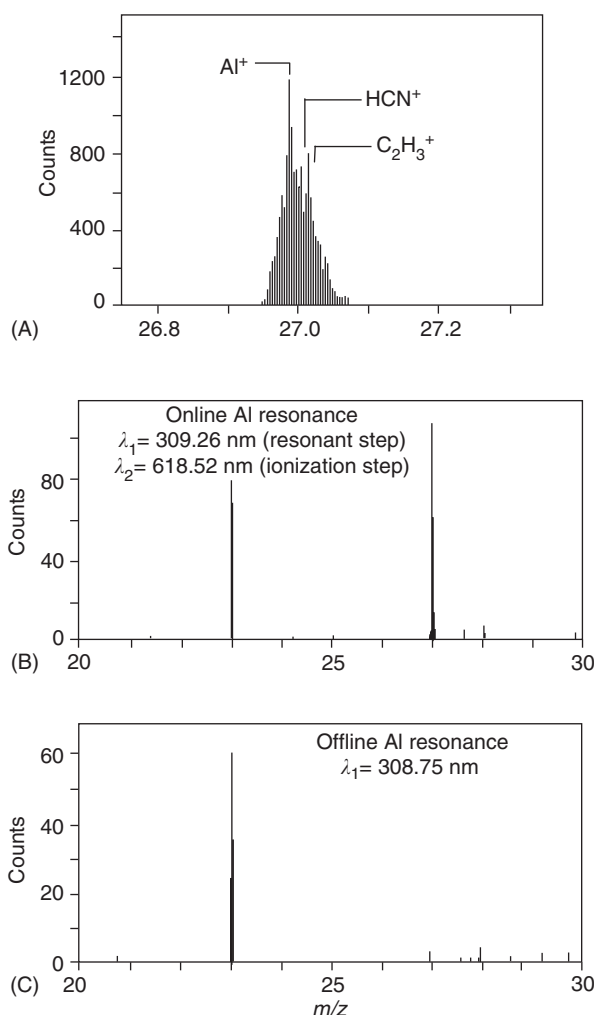

- Reduction of the matrix effects because ionization of neutrals in vacuum limits the interaction between constituents in the analyzed microvolume. Residual matrix effects are due to the sputtering step but remain orders of magnitude smaller than those for directly emitted secondary ions. Hence, quantification in SALI is by far less demanding with respect to calibration standards than SIMS.
- Elimination of isobaric interferences by the ionization itself, allowing lower mass resolution and higher transmission to be used in comparison with SIMS.

Figure 5 surveys the elements that can be addressed by laser postionization involving either SPI or MPI. The initial excitation of sputtered neutrals makes the investment of money and experimental efforts for RI often not paying in SNMS. In contrast, NR conditions are ideal for surveying the elemental composition. A typical example is the analysis of gallium arsenide, illustrated in Figure 6. The significant difference of  $I_{\text{SIMS}}$  for Ga in an As matrix and As in a Ga matrix hampers the quantitative analysis of major component analysis by means of the directly emitted secondary ions. In contrast, application of SALI yields peak intensities that correlate directly with the stoichiometric ratio of Ga and As over a wide range of compositions.

Figure 7 illustrates the advantage of SALI in comparison to SIMS for the detection of  $\text{Al}^+$  in a brain tissue sample. Use of the directly emitted secondary ions in the analysis of a sample containing 500  $\mu\text{g}$  per g Al requires the  $\text{Al}^+$  ions ( $m/z$  26.98) to be separated from the isobars due to  $^{26}\text{MgH}^+$  ( $m/z$  26.99),  $\text{C}^{15}\text{N}^+$  ( $m/z$  27.00),  $\text{HCN}^{+\bullet}$  ( $m/z$  27.01),  $\text{C}_2\text{H}_3^+$  (27.02). The presence of the first two interfering ions has been verified with high mass resolution mass spectrometry but cannot be traced back in the TOF-MS signal. The peak overlap prevents accurate quantification of the Al contribution. Application of an REMPI scheme in SALI eliminates the interfering ions and brings the detection limit to  $\sim 3$   $\mu\text{g}$  per g (resonant  $\lambda$  of 309.26 nm).

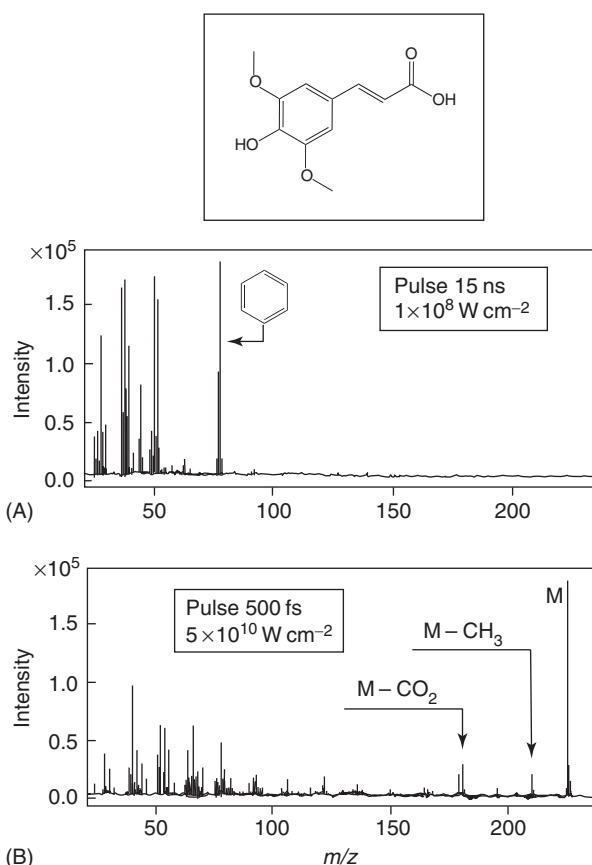

The relative insensitivity of SALI to matrix effects in comparison to SIMS makes the method particularly suited to the characterization of surface coatings, e.g., inorganic overlayers of nitrides and oxides, intentionally or accidentally deposited organic layers on an inorganic surface. Continuing bombardment of the sample with an ion dose above

**Figure 7** Positive ion mass spectra detected from a cortical tissue sample. (A) Isobars present detected around  $m/z$  27 in the SIMS mode without postionization. Mass spectra recorded using postionization under resonance (B) and nonresonant (C) conditions. (Reprinted from Jones OR, Perks RM, Abraham CJ, Telle HH, and Oakley AE (1997) A comparison of the techniques of secondary ion mass spectrometry and resonance ionisation mass spectrometry for the analysis of potentially toxic element accumulation in neural tissue. *Rapid Communication in Mass Spectrometry* 11: 179–183; © John Wiley.)

organic applications with SALI. Specifically, the latter team has pioneered the use of REMPI for post-ionization of the neutrals generated by primary ion bombardment of (sub-)monolayers of polyaromatic hydrocarbons. The sensitivity of SALI experiments has exceeded that of SIMS by a factor of 100. Detection limits in the femtomole range have been reached for fragile biomolecules, such as tryptophane, serotonin, and  $17\beta$ -oestradiol, deposited on silicon. **Figure 8** illustrates the significant gain in molecular information obtained even in the case of the simple molecule sinapinic acid by the application

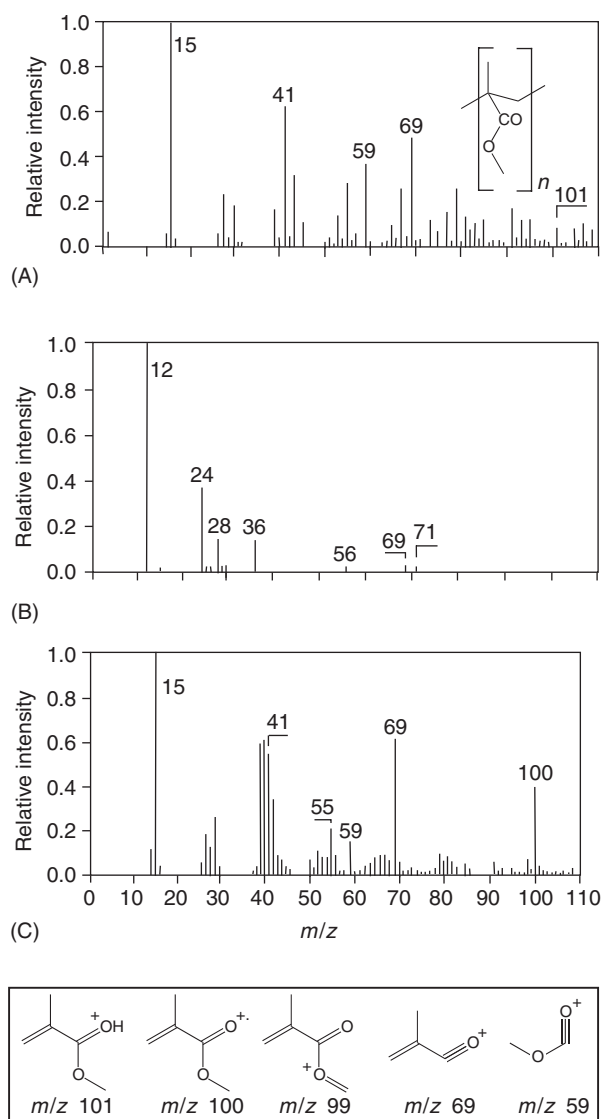

**Figure 8** Positive ion mass spectra taken from sinapinic acid using primary ion beam sputtering and laser postionization with 15 ns (A) and 500 fs (B) pulses of  $\lambda = 248$  nm. (Reprinted from Möllers R, Terhorst M, Niehuis E, and Benninghoven A (1992) Resonant photo-ionisation of sputtered organic molecules by femtosecond UV laser pulses. *Organic Mass Spectrometry* 27: 1393–1395.)

of 500 fs instead of 15 ns laser pulses ( $\lambda = 48$  nm). Ultrafast MPI with subnanoseconds laser pulses offers a particularly interesting potential for the analysis of labile substances such as organometallics and large biomolecules.

The use of an SPI scheme for the laser postionization of ion beam sputtered neutrals from polymers reduces the fragmentation in comparison to MPI-SALI. **Figure 9** compares the positive ion mass spectra recorded by S-SIMS, SALI, with SPI ( $\lambda = 118$  nm) and MPI (248 nm). Whereas an S-SIMS detects a small signal due to the protonated monomer, SALI with MPI exhibits extensive fragmentation causing the complete loss of the parent ion signal. In contrast, the limited fragmentation in SALI with SPI allows fragmentation the  $\text{M}^{+\bullet}$  of the monomer at  $m/z$  100 to be seen.

**Figure 10** illustrates the difference between the S-SIMS and SALI mass spectra of pyrene butyric acid,

**Figure 9** A comparison of the positive ion mass spectra obtained from the surface of polymethylmethacrylate (PMMA) with  $\text{Ar}^+$  primary ions in the SIMS mode without postionization (A) and with laser postionization (B and C) using MPI ( $\lambda = 248 \text{ nm}$ , power density of  $10^7 \text{ W cm}^{-2}$ ) and SPI ( $\lambda = 118 \text{ nm}$ , power density =  $3 \times 10^3 \text{ W cm}^{-2}$ ), respectively. The structural assignment of major diagnostic ions is illustrated at the bottom. (Figure (A) is reproduced from Brown A and Vickerman JC (1986) A comparison of positive and negative static SIMS spectra of polymer surfaces. *Surface and Interface Analysis* 8: 75–81; and Figure (B) is reproduced from Pallix JB, Schuhle U, Becker CH, and Huestis DL (1989) Advantages of single photon ionisation over multiphoton ionisation for mass spectrometric surface analysis of bulk organic polymers. *Analytical Chemistry* 61: 805–811.)

bound to silver beads on a silicon substrate. The directly emitted secondary ions give virtually no signal in the molecular weight region and deprotonated methylpyrene fragments at  $m/z$  215 must be used to characterize the presence of the ad-layer. In contrast,

MW288

**Figure 10** Positive ion mass spectra of pyrene butyric acid desorbed from silver beads without (A) and with (B) laser postionization by means of 250 fs pulses at  $\lambda = 266 \text{ nm}$ . (Reprinted from Willey KF, Vorsa V, Braun RM, and Winograd N (1998) Postionization of molecules desorbed from surfaces by KeV ion bombardment with femtosecond lasers. *Rapid Communications in Mass Spectrometry* 12: 1253–1260.)

the intensity of the  $\text{M}^{+\bullet}$  signal in SALI is still 50% of the base peak due to the deprotonated methylpyrene. As a result, it has been possible to visualize the distribution of organic molecules at the surface of beads with a diameter of 40–100  $\mu\text{m}$  in the form of a ‘chemical’ image, in which the brightness and contrast directly reflects the abundance of a specific substance in the upper monolayer at the surface.

## Future Developments

The proliferation of adequate lasers and commercial TOF-SIMS instruments with advanced features for focused primary ion bombardment under static conditions, highly efficient mass analysis, and detection

as well as imaging is expected to make the virtues of SALI increasingly appreciated in material analysis. The recent use of polyatomic primary ions for increased sputtering yields with low ion-beam induced damage of the subsurface, which emerges as the most promising development in S-SIMS, has not been explored yet in SALI but ultimately offers increased possibilities for molecular detection and depth profiling of organic materials. At this moment, SALI is often considered as a niche technique to be exploited for the tasks that S-SIMS cannot handle because of isobaric interferences. The selectivity of RI and REMPI schemes reduces the need for high mass resolution. Simple TOF analyzers with high transmission and thereby favorable detection sensitivity are adequate. The laser postionization often yields a significant gain in ion yield in comparison to the direct emission of secondary ions in (S-)SIMS. The advent of ultrafast lasers with pulse durations in the subnanosecond range is foreseen to give additional impetus to the use of SALI in a variety of material science applications that require the characterization of the molecular composition and structure of the analytes in the ultimate surface layers.

### Introduction

A diffraction experiment designed for crystal structure analysis requires a probe with de Broglie wavelength shorter than the interatomic spacing of the solid. The wavelength of an electron of energy  $E$  is given by  $E = (h/\lambda)^2/2m$ , and thus it is convenient to estimate the wavelength from the relation  $\lambda = 1.23/\sqrt{E}$  (nm), where the energy  $E$  is given in electronvolts. This indicates that wavelengths of electrons with energies of 20–300 eV, which are commonly called low-energy electrons, are 0.071–0.28 nm and thus meet the requirement for diffraction experiment. **Figure 1** shows the average mean free paths of electrons inside a solid (universal curve) in the energy range of 2–10 000 eV. As shown in **Figure 1**, the mean free path of low-energy electrons is in a range of 0.1–1 nm, a length that corresponds to a few atomic layers at low-index surfaces. The coincidence of the ideal wavelength and the surface sensitivity forms the basis for low-energy electron

diffraction (LEED) from solid surfaces. When low-energy electrons are reflected from an ordered crystal surface, the elastically backscattered electrons are distributed according to the two-dimensional (2D) grid of the surface and will form a Fraunhofer diffraction pattern. The Fraunhofer diffraction pattern is the Fourier transform of the surface atom arrangement, and thus it reflects the symmetry and the crystalline order of the surface. The qualitative

### Introduction

A diffraction experiment designed for crystal structure analysis requires a probe with de Broglie wavelength shorter than the interatomic spacing of the solid. The wavelength of an electron of energy  $E$  is given by  $E = (h/\lambda)^2/2m$ , and thus it is convenient to estimate the wavelength from the relation  $\lambda = 1.23/\sqrt{E}$  (nm), where the energy  $E$  is given in electronvolts. This indicates that wavelengths of electrons with energies of 20–300 eV, which are commonly called low-energy electrons, are 0.071–0.28 nm and thus meet the requirement for diffraction experiment. **Figure 1** shows the average mean free paths of electrons inside a solid (universal curve) in the energy range of 2–10 000 eV. As shown in **Figure 1**, the mean free path of low-energy electrons is in a range of 0.1–1 nm, a length that corresponds to a few atomic layers at low-index surfaces. The coincidence of the ideal wavelength and the surface sensitivity forms the basis for low-energy electron

diffraction (LEED) from solid surfaces. When low-energy electrons are reflected from an ordered crystal surface, the elastically backscattered electrons are distributed according to the two-dimensional (2D) grid of the surface and will form a Fraunhofer diffraction pattern. The Fraunhofer diffraction pattern is the Fourier transform of the surface atom arrangement, and thus it reflects the symmetry and the crystalline order of the surface. The qualitative

**Figure 1** Electron mean free path.

observation of the diffraction pattern is widely used to determine the periodicity and the symmetry of the surface structure and to identify ordered adsorbate phases.

The application of LEED is limited to ultrahigh vacuum (UHV) conditions because of the character of the probe and its high surface sensitivity. The main application is the study of single crystal metal and semiconductor surfaces, and adsorption on these surfaces. Study of surfaces of thin insulator films is also possible. Recently, the application extends to study the surface structure of quasicrystals. LEED is widely applied to determine the symmetry and periodicity of surface structures and thus to identify reconstructions and adsorbate phases by observing the diffraction pattern. It is also a technique for quantitative surface structure analysis. LEED is also applied as the quantitative determination of thermal vibrations at surfaces.

## Diffraction from Surfaces

A solid surface is intrinsically an imperfection of a crystalline solid by destroying the three-dimensional (3D) periodicity of the structure. That is, the unit cell of a crystal is usually chosen such that two vectors are parallel to the surface and the third vector is normal or oblique to the surface. Since there is no periodicity in the direction normal or oblique on the surface, a surface has a 2D periodicity that is parallel to the surface. By considering the symmetry properties of 2D lattices, one obtains the possible five 2D Bravais lattices shown in **Figure 2**. The combination of these five Bravais lattices with the 10 possible point groups leads to the possible 17 2D space groups. The symmetry of the surface is described by one of these 17 2D symmetry groups.

Surfaces frequently form superstructures by reconstruction and/or by adsorbate. The unit cells of these surface superstructures are usually describe by using the unit cell of the truncated bulk structure as  $(n \times m)$  or  $(n \times m)R\alpha^\circ$ , where  $n$  and  $m$  are integers or square

roots of integers that give the factors by which the translation vectors of the surface unit cell are enlarged compared to the bulk unit cell, and  $R\alpha^\circ$  denotes the rotation of the unit cell with respect to the substrate unit cell.

If an electron beam with wave vector  $\mathbf{k}_0$  is incident on a 2D system and the wave vector of the diffracted electron is  $\mathbf{k}_g$ , the conservation of energy gives

$$k_{0\parallel}^2 + k_{0\perp}^2 = k_{g\parallel}^2 + k_{g\perp}^2 \quad [1]$$

The suffixes  $\parallel$  and  $\perp$  denote the components parallel and perpendicular to the surface. The conservation of momentum gives

$$\mathbf{k}_{g\parallel} = \mathbf{k}_{0\parallel} + \mathbf{g}_{hk} \quad [2]$$

$\mathbf{g}_{hk}$  is a vector of the 2D reciprocal lattice

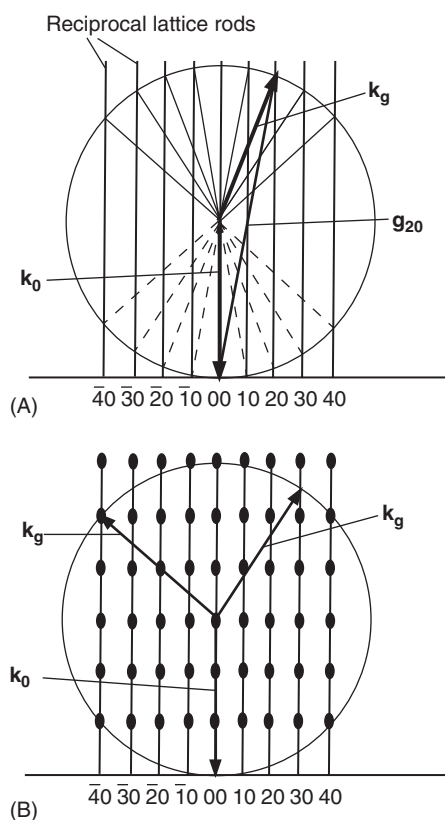

$$\mathbf{g}_{hk} = h\mathbf{a}^* + k\mathbf{b}^* \quad [3]$$

where  $\mathbf{a}^*$  and  $\mathbf{b}^*$  are the vectors of the reciprocal unit cell and  $h$  and  $k$  are integers. A convenient graphical representation of these Laue conditions in reciprocal space is the Ewald sphere construction. **Figure 3A** shows the Ewald construction for an electron beam incident normal to the surface. The wave vector of the incident electron beam,  $\mathbf{k}_0$ , is positioned with its end at the (00) reciprocal lattice point and a sphere with radius  $k$  is constructed around its starting point. Any line from the center of the sphere to the intersection point of the sphere and a reciprocal lattice rod represents a diffracted beam. One diffracted beam,  $\mathbf{k}_g$ , is shown in **Figure 3A** together with its associated reciprocal lattice vector  $\mathbf{g}_{20}$ . The diffracted beams are thus characterized by the index of the reciprocal lattice rods ( $hk$ ).

The presence of random steps or islands destroy the perfect 2D periodicity of the surface and thus the delta function character of the reciprocal lattice rods. Furthermore, the finite penetration depth of the low-energy electrons allows diffraction from not only the outermost atomic layer, but also from the 3D surface 'region'. This 3D scattering forms thicker regions in the reciprocal lattice rods according to the 3D Laue condition (**Figure 3B**). When the Ewald sphere crosses a thicker region, the diffracted beam has a strong intensity, and the intensity of the diffracted beam is weaker when the sphere crosses a thinner region. In the condition shown in **Figure 3B**, the intensities of the  $(\bar{4}0)$  spot and the  $(40)$  spot are stronger than the intensities of other spots. This leads to an important application of LEED. By changing the energy of the incident electron beam, one can change the radius of the Ewald sphere. The Ewald sphere passes through stronger and weaker regions of the rods as its radius

**Figure 2** The five 2D Bravais lattices.

**Figure 3** Ewald sphere construction for an electron incident normal to the surface on (A) a perfect 2D system and (B) a quasi-2D system. In (A), the reciprocal lattice vector  $\mathbf{g}_{20}$  is shown associated with the relevant scattered wave. The dashed scattered wave vectors propagate into the bulk and thus are not observable.

varied. Measuring the intensity of a diffracted beam as a function of energy (the  $I/V$  curve ( $I$ , intensity;  $V$ , accelerating voltage of electrons)) and comparing the experimental result with model calculations is a usual method of structure analysis. A typical  $I/V$  curve is shown in Figure 4.

Although the most common  $I/V$  curve measurement is performed at normal incidence because the symmetry can be used to orient the sample, the intensity distribution in reciprocal space may also be measured by rotating the crystal about the surface normal or by changing the angle of incidence. However, these modes are rarely used, because of the experimental difficulty to measure the angles precisely.

## LEED Experiment

The first step in LEED experiments is the surface preparation. A surface with atomic-scale flatness is achieved by annealing a single crystal sample, which has a thickness of less than 1 mm and has at least one

**Figure 4** A typical LEED  $I/V$  curve.

face well oriented in the desired crystallographic orientation. Ion sputtering followed by additional annealing are used to remove impurities adsorbed on the surface and thus to obtain a clean ordered surface. Ordered adsorbate surfaces can be obtained by the adsorption of a monolayer or submonolayer of atoms or molecules onto the clean surface. The quality of the clean surface and/or the adsorbate surface is characterized using Auger electron spectroscopy (AES), X-ray photoelectron spectroscopy, and LEED.

## General Features

LEED experiments are usually performed in a UHV chamber that is maintained at pressures below  $10^{-10}$  mbar ( $\sim 10^{-8}$  Pa). The maintenance of a sufficiently low pressure is important to avoid residual gas adsorption and thus to keep the surface free of impurity during the measurement. In fact, a surface can be contaminated by a monolayer of gas in  $\sim 1$  s with a sticking coefficient of 1 with an ambient pressure of  $10^{-6}$  mbar. Thus, the timescale of the experiment may be estimated to be  $\sim 1000$  s before the surface is contaminated with one monolayer of the residual gas.

The quantitative measurement of diffracted intensities requires a planar and homogeneous surface of several  $\text{mm}^2$  in area and the sample must be orientated to within  $0.1^\circ$ . Furthermore, the earth magnetic fields must be balanced or shielded since it can deflect low-energy electrons. In addition, sample preparation requires heating to high temperatures to cleaning, whereas it is desirable to cool down the sample to liquid nitrogen temperature or below to reduce the thermal diffuse scattering in the case of intensity measurements.

### Experimental Setup

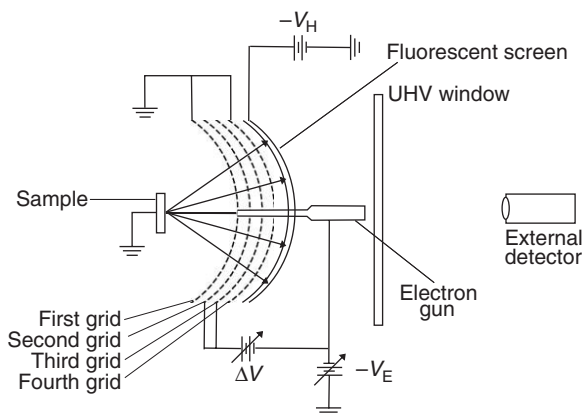

There are several experimental setups in use. The apparatus most commonly used to display the LEED pattern is a display setup where the diffracted electron beam is made visible on a fluorescent screen. Typically, the display setup consists of three or four hemispherical concentric grids that act as a high-pass filter for the inelastic scattered electrons. The four-grid systems can also be used for AES measurements to control the cleanliness of the surface. A schematic drawing of a back viewing arrangement of a four-grid system with an external detector is shown in **Figure 5**. This arrangement has the advantage that the grids and the sample holder do not hinder the observation of the diffraction pattern, and additional experimental tools near the crystal sample do not shadow the screen. The first grid is connected to earth ground to provide an essentially field-free region between the sample and the first grid, which minimizes the electrostatic deflection of diffracted electrons. A suitable potential ( $-V_E + \Delta V$ ) is applied to the second and third grids to retard inelastically scattered electrons. The fourth grid is grounded to reduce the field penetration of the second and third grids that can originate from the high potential ( $V_H$ , usually a few kilovolts) applied to the fluorescent screen. A typical diffraction pattern at normal incidence is shown in **Figure 6**.

The primary beam current is usually in the order of  $1\ \mu\text{A}$ , with an energy spread of  $\sim 0.5\ \text{eV}$ . This current density is rather high and materials that are sensitive to electron (for example, molecular overlayer structures) or insulator surfaces may suffer severe damage. For this purpose channel plates are used either in front of a fluorescent screen or in front of a position-sensitive detector, to intensify the diffracted beam. The use of two channel plates amplify the

diffracted beam current by a factor of  $\sim 10^7$ , and thus allows the primary beam current to be in the order of  $0.1\text{--}1\ \text{nA}$ . The current of the diffracted beam is usually in the order of  $10^{-2}\text{--}10^{-4}$  of the primary beam and can be measured directly with a video camera from the fluorescent screen. By using the channel plate equipped system, the time required to measure the intensity of a diffracted beam at a particular energy is 20 ms, and the measurement of a complete set of  $I/V$  curves is less than 20 s.

### LEED Pattern

LEED pattern shows directly the size and orientation of the surface unit cell. However, the symmetry of the unit cell is not necessarily identical to the experimentally observed symmetry in LEED including spot intensities. The properties of symmetries such as rotation axes or mirror planes affect the intensities of the spots. The distinction between the structural symmetries of the surface and symmetries observed among spot intensities in LEED can be performed by changing the direction of the incident electron beam. At oblique incidence only mirror planes can be observed when the incident beam is parallel to the symmetry plane, otherwise the diffraction pattern exhibits no symmetry. In cases where the surface is not well ordered one may obtain additional symmetry information from the diffused LEED spots. The characteristic distribution of diffuse intensity in reciprocal space indicates the existence of short-range ordered antiphase domains or twin domains.

**Figure 5** Schematic diagram of a four-grid LEED display system.

**Figure 6** LEED pattern of the reconstructed  $\text{Si}(111)\text{--}(7\times 7)$  clean surface.

The analysis is analogous to that in diffuse X-ray diffraction.

### Domains

Rotational, translational, and mirrored domains are prevalent in the presence of adsorbate superstructure or adsorbate-induced reconstruction. A surface structure with symmetry lower than the symmetry of the substrate can produce such domains by applying all symmetry operations of the substrate. Since different domains with the same internal structure have the same structural energy, these domains should have an equal existence probability on a surface. If the areas of any domains presented on the surface are larger than the lateral coherence length of the incident electron beam, which is typically in the order of few tenths of a nanometer, the LEED pattern becomes the sum of the individual diffraction patterns of each domain. However, in cases where the symmetry of the surface is distorted by steps or by a strain, it is possible to eliminate certain domains selectively and one domain becomes dominant. **Figure 7A** shows an example of a well-oriented surface that contains three rotational domains, and **Figure 7B** displays a one-domain sample obtained using a stepped surface.

### Glide Plane Symmetry

Glide planes can be identified by the systematic absence of odd-order reflections in the glide plane. **Figure 8** shows the LEED pattern of a surface with a glide plane symmetry, in which spot extinctions are clearly observed along some lines. The absence of spots occurs when the direction of the incident electron beam is normal to the surface and when it is parallel to a glide plane of the surface. In some cases, there are invisible weak spots though there is no glide plane symmetry on the surface. However, this kind of missing spots and the extinctions due to glide lines can be distinguished by changing the direction of the incident electron beam because they have a different incident angle dependence, and by considering the

positions of the missing spots because they occur at different positions. In the case of a single domain surface, the direction of the lines of missing spots indicates directly the orientation of the glide lines. When different domains exist on the surface, even though one domain produces missing spots, other domains can give nonzero intensities at those positions. This problem can be solved by changing the sizes of domains that leads to an asymmetry in the spot intensities.

### Structural Analysis

Together with the determination of the symmetry and the periodicity of the surface structure, the atomic arrangement of the surface, the surface composition, and the thermal vibrations at surfaces can be determined by a quantitative analysis of the diffracted intensities. In most cases, the  $I/V$  curves are used for quantitative analysis. The small penetration depth of low-energy electrons restricts the applicability of the technique to  $\sim 1$  nm depth. Due to the large atomic scattering cross-section for low-energy electrons in a solid, the kinematic scattering theory does not describe the diffracted LEED intensities correctly, and thus a dynamical theory calculation is necessary for the quantitative description of diffraction intensities. In this context, the term dynamical is used synonymously for multiple scattering, in contrast to the kinematical theory that considers single scattering only. The dynamical theory of X-ray diffraction is, in principle, equivalent to the

**Figure 7** LEED patterns of (A) a three-domain  $\text{Si}(111)-(3 \times 1)$  surface and (B) a single-domain  $\text{Si}(111)-(3 \times 1)$  surface.

**Figure 8** LEED pattern of a three-domains  $\text{Si}(111)-(6 \times 1)$  surface.

dynamical theory of electron diffraction, but differs in the formulation of multiple scattering processes. This difference leads to the fact that it is not possible to invert LEED experimental data directly to obtain the atomic structure of the surface, like using the Patterson function in X-ray diffraction (the use of the Patterson function is based on the applicability of the kinematic theory). The structural analysis using LEED is conventionally done by comparing the measured intensities with the model calculations using a full dynamical theory. Tensor LEED is a perturbation method for calculation of the diffraction intensities in the vicinity of a reference structure, and has the advantage of a very fast calculation. The essential ingredients of the multiple scattering processes are the ion core scattering, the multiple scattering, the inelastic scattering, and the temperature effects.

### Multiple Scattering

The calculation of the diffracted intensities usually proceeds in two steps. The first step is the construction of the crystal potential and the calculation of the scattering amplitudes from a single atom, and the second step is the calculation of scattering processes within a single atomic layer and the calculation of scattering between different atomic layers. In the second step the multiple scattering processes are based on the condition that the scattered wave from one atom is an incident wave on all other atoms. This leads to a set of linear equations that is solved by matrix inversion. The formulation of the theory is based on the KKR (Korringa-Kohn-Rostocker) method used for band structure calculations.

A muffin-tin model (Figure 9), in which spherically symmetric ion core scattering potentials are truncated at the radii at which they just touch and the interstitial region is assumed to be at a constant potential (muffin-tin constant), is often used for the first step. The crystal potential is obtained from a superposition of free atom electron densities that is spherically averaged inside the muffin-tin sphere. The muffin-tin constant cannot be calculated precisely enough and is treated as a variable parameter in the calculation. Its energy dependence is frequently included assuming that of the free electron gas, but an energy-independent value is in use as well. Common values are in the range of 5–15 eV.

The scattered intensity is conventionally written as

$$I(\mathbf{k}_0, \mathbf{k}_g) = \left| \sum_v F_v(\mathbf{k}_0, \mathbf{k}_g) \exp[2\pi i(\mathbf{k}_0, \mathbf{k}_g) \mathbf{r}_v] \right|^2 \quad [4]$$

**Figure 9** Top and sectional views of a muffin-tin potential,  $V$ , which is conventionally used in LEED multiple scattering calculations.

that is, using an equation that is formally equivalent to the sum over scattered amplitudes used in the kinematical theory. The sum over  $v$  runs over all atoms in the surface at position  $\mathbf{r}_v$ .  $F_v(\mathbf{k}_0, \mathbf{k}_g)$  is a generalized scattering amplitude that relates the scattered wave leaving atom  $v$  to the incoming wave without further scattering. The difference between the dynamical and kinematic calculations is that in the kinematic calculation the scattering amplitude is a function of the scattering vector  $\mathbf{q} = \mathbf{k}_0 - \mathbf{k}_g$  and depends on the kind of the atom, whereas the scattering amplitude is an explicit function of both vectors,  $\mathbf{k}_0$  and  $\mathbf{k}_g$ , in the dynamical calculation. The generalized scattering amplitude is a complex number and both the modulus and phases of the amplitudes  $F_v(\mathbf{k}_0, \mathbf{k}_g)$  vary strongly with the atomic arrangement in the neighborhood as a result of multiple scattering.  $F_v(\mathbf{k}_0, \mathbf{k}_g)$  can be calculated starting from the single scattering amplitude from a spherically symmetric atom. The scattering from a spherically symmetric potential is given by the solution of the Schrödinger equation that can be calculated numerically, and the scattering amplitudes are given by

$$f(\mathbf{k}, \mathbf{k}') = \frac{-2\pi i}{k} \sum_l (2l+1) [\exp(2i\delta_l) - 1] P_l(\cos \theta_{k,k'}) \quad [5]$$

where  $\theta_{k,k'}$  is the angle between the vectors  $\mathbf{k}$  and  $\mathbf{k}'$ . The quantities  $\delta_l$  which are used as input parameters, are the phase shifts of the spherical waves and describe the scattering properties of the atom. Usually, 6–10 phase shifts are included in the calculation. This number increases with the energy and atomic number of the atom.

### Inelastic Scattering

Inelastic scattering proceeds to the damping of an electron wave as

$$\Psi \sim \exp(-r/\lambda) \exp(ik_r r) \quad [6]$$

where  $k_r$  is the real part of a complex  $k$  that describes the damping. This equation indicates that the damping effect correlates to the mean free path  $\lambda$ . By regarding  $k$  as a complex energy, the relation between  $\lambda$  and the imaginary component of energy  $V_i$  is

$$\lambda \approx 0.39E^{1/2}/V_{0i} \quad [7]$$

where  $E$  and  $V_{0i}$  are expressed in electronvolts and  $\lambda$  in nanometers. In calculation, either  $\lambda$  or  $V_{0i}$  is usually kept constant for convenience.

### Thermal Effects

Thermal vibrations reduce scattering coherence and therefore reduce the intensities of diffracted electron beams. An atomic scattering factor is reduced by

$$\exp(-\frac{1}{2}\Delta k^2 \langle u^2 \rangle) = \exp(-M) \quad [8]$$

$\langle u^2 \rangle$  is the mean square vibrational amplitude measured in the direction of  $\Delta k$  and  $M$  is the Debye-Waller factor. The thermal effects affect the relative peak intensities, and contributes to reducing multiple scattering.

### Comparison with Experimental Data

A number of different  $R$ -factors are currently in use to quantify the agreement between experimental and theoretical  $I/V$  curves. There is no consensus as to which is the most appropriate. The most commonly used  $R$ -factor is  $R_p$  (the Pendry  $R$ -factor),  $R_1$  and  $R_2$  (the most common X-ray  $R$ -factors), and  $R_{ZJ}$  (the Zanazzi-Jona  $R$ -factor). The definition of Pendry  $R$ -factor is

$$R_p = \frac{\int (Y_e - Y_t)^2 dE}{\int (Y_e^2 + Y_t^2) dE} \quad [9]$$

with

$$Y = L/(1 + V_{0i}^2 L^2) \quad [10]$$

where  $L = l'/l$  is the logarithmic derivative of the  $I/V$  curve, and  $V_{0i}$  is the imaginary part of the electron self-energy. A value of  $R_p$  below 0.2 can be considered as good-to-excellent agreement, 0.3 indicates average agreement, and above 0.4 the agreement is marginal. With low-index beams and in the lower-energy range the level of agreement is in general better than for high-index beams and high energies.

$R_1$  and  $R_2$  are defined as

$$R_1 = \frac{\int (l_e - c_l) dE}{\int l_e dE} \quad [11]$$

$$R_2 = \frac{\int (l_e - c_l)^2 dE}{\int l_e^2 dE} \quad [12]$$

with

$$c = \frac{\int l_e dE}{\int l_t dE} \quad [13]$$

Both can be defined as integrals over continuous curves as well as sums over discrete points. In the latter case  $R_1$  has been called  $R_{DE}$ .

$R_{ZJ}$  is defined empirically by a more complicated expression using the second derivative of the  $I/V$  curves. The second derivative is used from the fact that the maxima are frequently not clearly separated. A disadvantage of using  $R_{ZJ}$  is that its absolute value depends on the energy range. It is therefore less frequently used. To avoid local minima in the  $R$ -factor curves it has been found that an average of different  $R$ -factors can be used to provide a more pronounced minimum.

### Accuracy of the Structure Determination

The error bars of the structure analysis are difficult to estimate because of the unknown influence of the approximations used in the LEED theory. Together with the main unknown factors, the nonspherical ion core potentials, anisotropy and energy dependence of inelastic scattering, and anisotropy and correlation effects of the thermal vibrations, there are further uncertainties due to systematic errors in the experimental data, misalignment of the surface orientation, and imperfections in the surface structure. The precision of the analysis is frequently estimated from the sensitivity of the  $R$ -factors to a variation of structural parameters assuming statistical errors. The standard deviation of the structural parameters is calculated from the number of beams and the energy range, assuming an average density of peaks in the  $I/V$  curves. For the back-scattering geometry, the highest precision is obtained for the outermost surface atoms and the precision becomes smaller for atoms in deeper layers. The estimated error is usually 0.001–0.003 nm for the layer distances and 0.005–0.01 nm for the parallel components of the atomic positions in the top two layers.

### Application of LEED

The relatively simple LEED experiment and the fact that LEED systems are commercially available have

led to a broad application in surface science. One of the main advantages of the LEED method is that the whole diffraction pattern is visible on a screen. A qualitative interpretation of the diffraction pattern is the most common use of LEED. It allows the surface unit cell to be identified, the state of order to be estimated, and surface phases in adsorption systems to be identified. The observations of 1D and 2D phase transitions are also performed using LEED. Quantitative structure analyses have mainly been performed for metal surface and adsorbate layers on metals. Surface defect distributions and structure of disordered adsorbate layers are performed by analyzing the angular beam profiles in the diffuse background. In the study of defect distributions the kinematic theory of diffraction can be applied as long as only the shapes of the profiles are evaluated and not the intensities. Multiple scattering effects are short-ranged, and the mean free path is of the order of several interatomic distances, so that for sufficiently widely spaced defects multiple scattering effects can be neglected. The main application of the study of defects has been the determination of step distributions in homo- and heteroepitaxial systems.

#### **Diffuse LEED (DLEED)**

The large cross-section of low-energy electrons makes it possible to measure the diffuse elastic background intensity arising from point defects. There are two methods to measure the background intensity. The first method is measurement of the spatial distribution of background intensity at different energies, and the second method is measurement of the energy dependence of the background intensity at certain points in the 2D reciprocal unit cell. The spatial distribution of background intensity can be measured using a fluorescent screen or a channel plate. After subtracting the diffuse scattering of the clean surface, the intensity distribution arising from point defects, which is formed by, for example, the adsorption of single atoms or molecules, can be analyzed quantitatively. To eliminate the effect of correlated defects that lead to maxima in the intensity distribution, the Y-function shown in eqn [10] is analyzed. The main uncertainty in this method is the subtraction of the thermal diffuse background. For the calculation of the energy dependence of the background intensity, conventional LEED programs can be used by modeling a defect site with a single atom or molecule in a large unit cell.

#### **Very-Low-Energy Electron Diffraction**

In the energy range between 0 and 10 eV, only the specularly reflected beam can be observed if the

surface unit cell is not too large. Very-low-energy electron diffraction (VLEED) is restricted to the measurement and analysis of the reflectivity. The advantages of the method are that (1) the intensity of the reflected beam in this energy range is high and (2) the experiment is relatively simple to perform. Because the reflectivity depends sensitively on the shape of the potential barrier across the surface, the method is used to study the potential barrier. A further advantage is the sensitivity to light elements such as hydrogen. A well-ordered superstructure is not required. The calculation of the reflectivity in this energy range is not very time-consuming because few beams and few phase shifts are required in the multiple scattering calculations. Special care has to be taken, however, to take account of the small optical potential at energies below the plasmon threshold. This makes conventional programs inapplicable for VLEED. Applications of the method include the study of surface resonances. VLEED has also been applied to locate hydrogen atoms at surfaces, to study disordered surfaces, and to eliminate models for which the full dynamical calculation at higher energies would be too tedious. The disadvantage of the method is the small database, which does not allow the study of complex structures.

### **Comparison with Other Related Surface Structure Analysis Techniques**

A number of techniques are used to determine structures of surfaces. These are (1) microscopic methods: scanning tunneling microscopy, atomic force microscopy; (b) spectroscopic methods: photoelectron diffraction, surface X-ray diffraction (XRD), extended X-ray absorption fine structure, and related techniques; and (3) ion scattering techniques: impact collision ion scattering spectroscopy, low-energy ion scattering, medium-energy ion scattering, and Rutherford back scattering. The microscopic methods have an advantage to obtain local surface structure in real space, but the information is limited to the arrangements of the outermost surface atoms. The technique that is most comparable to LEED is XRD. The main difference between LEED and XRD lies in the evaluation of the data. In the case of XRD, the kinematical diffraction theory is valid, which allows the application of structure analysis and refinement techniques developed for 3D structures, like the Patterson function, difference Fourier analysis, and the application of direct methods. XRD allows the determination of complicated surface structures that are not yet accessible with LEED. XRD is not limited to UHV conditions and in most cases

photon-induced damage is negligible. In practice, XRD requires intense sources. Mostly synchrotron radiation, but rotating anodes are also used for strongly scattering elements. The XRD experiment is more difficult to carry out as long measuring times are required and precision goniometers are necessary in UHV or precise movement of UHV chambers. With XRD, the full diffraction pattern cannot be observed. Most X-ray chambers as well as other surface structure instruments are therefore equipped with LEED screens to monitor the crystalline state of the surface. The resolution normal to the surface is not as high for XRD as for LEED as the momentum transfer normal to the surface at grazing incidence is limited to  $|\mathbf{k}|$ , while it is  $2|\mathbf{k}|$  in the case of LEED.

### Introduction

With the advent of sensitive Fourier transform infrared (FTIR) spectrometers, surface infrared spectroscopy has developed into one of the major surface analytical techniques. Highly specific information on molecular composition and structure, nondestructive sampling, and a fairly inexpensive instrumentation usable under ambient (nonvacuum) conditions are distinct advantages of IR spectroscopy over other surface science methods. Today, various surface-specific IR sampling techniques are available, which allow a wide variety of sample surfaces and adsorbate systems to be studied in the monolayer and sub-monolayer regime. They can be classified into reflection and nonreflection techniques according to the light path through the sample (**Figure 1**). The main reflection techniques are reflection absorption infrared spectroscopy (RAIRS), internal reflection or attenuated total reflectance (ATR), and diffuse reflectance infrared Fourier transform (DRIFT). Transmission measurements (TIR), emission

spectroscopy (EMS), and photoacoustic spectroscopy (PAS) are the most important nonreflective surface techniques. The optical properties of the sample (reflectivity, absorptivity) and its physical condition (powder, film, single crystal, etc.) will decide on which method to choose. RAIRS and ATR are typically used for the so-called low surface area samples (thin films or adsorbates on flat smooth surfaces) while powdered samples with a high surface area can be studied with DRIFT or transmission measurements of pressed pellets. EMS and PAS are the most versatile techniques regarding the sample properties and can be used for samples of any shape. Most of these methods are discussed in separate chapters of this Encyclopedia and this article will therefore focus on RAIRS. After a brief treatment of the theoretical background, instrumentation and signal processing techniques will be discussed. The main body of the text will then deal with some representative applications for surface analysis.

### Theory

A simplified model of three isotropic phases (**Figure 2**) shall be used to describe the light absorption process in a reflection-absorption experiment. The

photon-induced damage is negligible. In practice, XRD requires intense sources. Mostly synchrotron radiation, but rotating anodes are also used for strongly scattering elements. The XRD experiment is more difficult to carry out as long measuring times are required and precision goniometers are necessary in UHV or precise movement of UHV chambers. With XRD, the full diffraction pattern cannot be observed. Most X-ray chambers as well as other surface structure instruments are therefore equipped with LEED screens to monitor the crystalline state of the surface. The resolution normal to the surface is not as high for XRD as for LEED as the momentum transfer normal to the surface at grazing incidence is limited to  $|k|$ , while it is  $2|k|$  in the case of LEED.

### Introduction

With the advent of sensitive Fourier transform infrared (FTIR) spectrometers, surface infrared spectroscopy has developed into one of the major surface analytical techniques. Highly specific information on molecular composition and structure, nondestructive sampling, and a fairly inexpensive instrumentation usable under ambient (nonvacuum) conditions are distinct advantages of IR spectroscopy over other surface science methods. Today, various surface-specific IR sampling techniques are available, which allow a wide variety of sample surfaces and adsorbate systems to be studied in the monolayer and sub-monolayer regime. They can be classified into reflection and nonreflection techniques according to the light path through the sample (**Figure 1**). The main reflection techniques are reflection absorption infrared spectroscopy (RAIRS), internal reflection or attenuated total reflectance (ATR), and diffuse reflectance infrared Fourier transform (DRIFT). Transmission measurements (TIR), emission

spectroscopy (EMS), and photoacoustic spectroscopy (PAS) are the most important nonreflective surface techniques. The optical properties of the sample (reflectivity, absorptivity) and its physical condition (powder, film, single crystal, etc.) will decide on which method to choose. RAIRS and ATR are typically used for the so-called low surface area samples (thin films or adsorbates on flat smooth surfaces) while powdered samples with a high surface area can be studied with DRIFT or transmission measurements of pressed pellets. EMS and PAS are the most versatile techniques regarding the sample properties and can be used for samples of any shape. Most of these methods are discussed in separate chapters of this Encyclopedia and this article will therefore focus on RAIRS. After a brief treatment of the theoretical background, instrumentation and signal processing techniques will be discussed. The main body of the text will then deal with some representative applications for surface analysis.

### Theory

A simplified model of three isotropic phases (**Figure 2**) shall be used to describe the light absorption process in a reflection-absorption experiment. The

**Figure 1** Sample illumination in different surface sensitive infrared techniques.

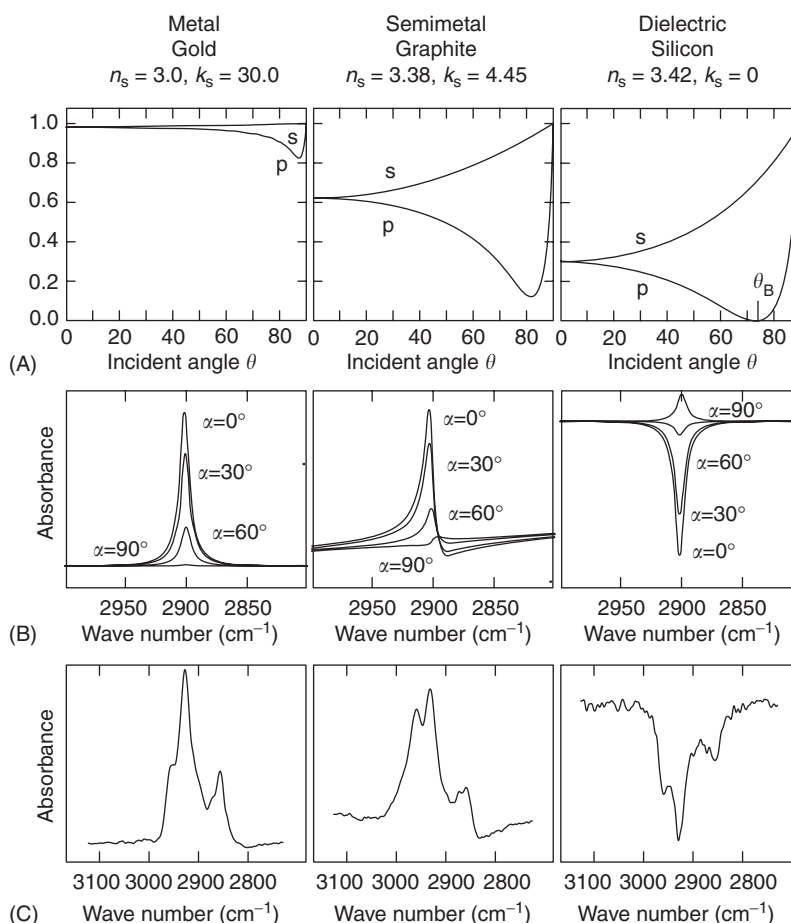

**Figure 2** Optical sample model for reflection absorption infrared spectroscopy.

optical properties of each phase are described by the complex refractive index  $\hat{n} = n + ik$  ( $n$  is the refractive index and  $k$  the absorption index). Phase 1 – the incident medium – is assumed to be air ( $n = 1, k = 0$ ), phase 2 is an adsorbate layer of thickness  $d$ , and phase 3 is the semi-infinite substrate phase. Infrared radiation (incident electric field  $E_1^i$ ) impinges on the surface at an angle  $\theta$  to the surface normal, bisects the adsorbate layer, and is reflected in the specular direction. The ratio  $\Delta R/R_0 = (R_0 - R_d)/R_0$  as a function of frequency, where  $R_d$  and  $R_0$  are the reflectivities of the adsorbate-covered and the bare substrate surface, respectively, and gives the reflection-absorption spectrum of the adsorbate. The theoretical treatment is based on calculations of the amplitude and phase changes of the electric field  $E$  of the incident radiation due to partial reflection and transmission at each interface and absorption by the

adsorbate. The calculations are carried out separately for light polarized perpendicular (s-polarized, where the s comes from the German word ‘senkrecht’, meaning perpendicular) or parallel (p-polarized) to the plane of incidence defined by the central incoming ray and the surface normal. The absorption intensities  $\Delta R = R_0 - R_d$  are determined by the so-called surface electric field, which is the vectorial sum of the incident and reflected electric field vectors  $E_2^i$  and  $E_2^r$  in the adsorbate layer, while the substrate reflectivity  $R_0$  is determined by the ratio  $E_1^r/E_1^i$  of the reflected to the incident electric field vectors for the bare substrate surface. Basic electromagnetic theory can be used to derive analytical expressions for the substrate reflectivity  $R_0$  and the absorption intensities  $\Delta R/R_0$  of an adsorbate as a function of the optical constants, the incidence angle, the layer thickness, and the frequency. In **Figure 3**, calculated and experimental RAIRS spectra of a hydrocarbon adsorbate film are compared on three different types of substrates. The main parameter, which determines the reflection properties of the substrate itself as well as the intensity and shape of an adsorbate vibrational absorption, is the absorption index  $k_s$  of the substrate, which can range from  $k_s = 0$  for nonabsorbing, dielectric substrates to  $k_s = 30$  for metal substrates. Thus, a strongly absorbing metal substrate ( $k_s > 10$ , e.g., gold) is compared in **Figure 3** with a weakly absorbing semimetal ( $1 < k_s < 10$ , e.g., graphite) and a nonabsorbing dielectric substrate ( $k_s = 0$ , e.g., silicon). **Figure 3A** first shows the reflectivities of the pure substrate as a function of the light incidence angle for s-polarized and p-polarized radiation, **Figure 3B** shows a calculated model absorption for p-polarized light at grazing incidence ( $80^\circ$ ) with different dipole moment tilt angles  $\alpha$  and **Figure 3C** shows experimental RAIRS spectra of thin, physisorbed hydrocarbon films on gold, graphite, and silicon. Without going into details, the following characteristics of RAIRS on different substrates are illustrated in **Figure 3**.

### Metal Substrate

The reflectivities for both s- and p-polarized light are  $\sim 1$  for all angles of incidence (**Figure 3A**). An adsorbate probed with p-polarized light yields symmetric, undistorted absorptions (**Figure 3B**), whose intensity is negligible for parallel dipole moment orientation ( $\alpha = 90^\circ$ ) and reaches a maximum for perpendicular orientation ( $\alpha = 0^\circ$ ). Thus, only the perpendicular component of a vibration, which is proportional to  $\cos \alpha$ , gives rise to absorption, because the electric field parallel to the surface is vanishingly small. The overall intensity is therefore

**Figure 3** Optical properties of three different substrate materials – a metal, a semimetal, and a dielectric – and their influence on IR reflection spectra of thin adsorbate films. (A) Substrate reflectivities of p-polarized (p) and s-polarized (s) radiation as a function of the light incidence angle  $\theta$ . (B) Simulated IR absorption of an adsorbate for different tilt angles  $\alpha$  of the vibrational transition dipole moment, probed with p-polarized light at 80° incidence. (C) Experimental CH stretching absorptions of a thin film of paraffin oil ( $d = 30$  nm), measured with p-polarized light at 80° incidence.  $n_s$  and  $k_s$  denote the refractive index and the absorption index of the substrate, respectively.

proportional to  $\cos^2 \alpha$ . This is the origin of the so-called ‘metal surface selection rule’, which can be used to determine surface orientations of molecules. A physisorbed adsorbate film with isotropic surface orientation yields a transmission-like, undistorted spectrum in a reflection absorption experiment (Figure 3C).

### Semimetal Substrate

With decreasing absorption index  $k_s$  of the substrate, the reflectivities for both s- and p-polarized light start to decrease and to diverge with  $R_p$  being always lower than  $R_s$  and going through a minimum  $\sim 80^\circ$  for the particular substrate (graphite) in Figure 3A. The simulated absorptions on graphite in Figure 3B are still quite similar to the metal substrate and yield a maximum peak intensity at  $\alpha = 0^\circ$  and only

minor absorption at  $\alpha = 90^\circ$ . The peakshape, however, shows a distinct asymmetry with a dip on the low-frequency side and a tail on the high-frequency side of the absorption, which is also visible in the experimental reflection spectra of Figure 3C. This asymmetry indicates the onset of the band inversion observed on dielectric substrates, which is caused by the adsorbate’s refractive index  $n$  dominating over the absorption index  $k$ .

### Dielectric Substrate

The reflectivity at normal incidence ( $\theta = 0^\circ$ ) is typically less than 30% (Figure 3A) and the p-polarized reflectivity goes to zero at the substrate’s Brewster angle  $\theta_B$  ( $\theta_B = \arctan n_s$ ). Perpendicular and parallel vibrational components give rise to absorptions of opposite ‘sign’, i.e., the corresponding peaks point in

opposite directions in the reflection spectrum. For incidence angles  $\theta > \theta_B$  as chosen in **Figure 3B** ( $\theta = 80^\circ$ ), the absorption points in the ‘negative’, downward direction for perpendicular dipole moment orientation ( $\alpha = 0^\circ$ ) and in the upward, regular direction for parallel orientation ( $\alpha = 90^\circ$ ). Consequently, the absorption vanishes for a certain tilt angle  $\alpha$ , where the perpendicular and parallel components cancel each other (e.g., at  $\alpha = 67^\circ$  for the example chosen in **Figure 3B**). A disordered, liquid-like film, where each dipole moment adopts an average orientational angle of  $\alpha = 54.7^\circ$  relative to the surface normal, therefore, yields an inverted absorption spectrum as shown in **Figure 3C**, where the band profiles are again undistorted as on metal substrates, but point in the opposite, downward direction.

## Instrumentation

### Optical Configuration

A typical setup for a reflection-absorption experiment is shown in **Figure 4**. IR radiation is passed from the spectrometer through a polarizer onto an off-axis paraboloidal mirror, which focuses the beam at an incident angle  $\theta$  onto the sample surface. A focal length  $> 15$  cm is advisable in order to keep the cone angle of the focused radiation at the sample surface small. From there the beam is reflected in the specular direction, is recollimated by a second off-axis paraboloidal mirror, and is focused onto the detector. Since a monolayer of an adsorbate on a smooth substrate is equal to only  $\sim 10^{14}$  mol cm $^{-2}$  surface area, the total amount of sample material probed by the light is very low (typically  $10^{-9}$  mol or less) and sensitivity is the major concern. The main

instrumental parameters and their influence on the signal-to-noise ratio (SNR) is briefly discussed below.

**Light source** Apart from the traditional blackbody sources for the mid-IR range ( $4000\text{--}400$  cm $^{-1}$ ) such as global, Nernst glower, ceramic sources, alternative brighter sources such as lasers, synchrotron radiation, or free electron lasers (FELs) are becoming available, which provide significant advantages for investigations of surfaces and interfaces. They provide highly focused, polarized radiation, which can be applied either in a continuous or in a pulsed mode with pulse durations from nanoseconds (synchrotron radiation) to femtoseconds (lasers, FELs). Despite some drawbacks such as the limited wave-number range of tuneable lasers, the high expense, and the usually complex instrumentation these novel sources open the access to a range of new experiments including time-resolved studies on surfaces (e.g., relaxation processes of excited vibrational and electronic states), surface imaging (e.g., near-field IR microscopy), and studies of low-energy vibrations (substrate-adsorbate binding vibrations, crystal lattice vibrations, etc.) in the far-IR region.

**Incidence angle** The SNR in a RAIRS spectrum is given by the absorption intensity  $\Delta R/R_0$  divided by the noise level, which in the mid-IR region ( $4000\text{--}400$  cm $^{-1}$ ) is inversely proportional to the reflectivity  $R_0$  of the substrate:

$$\text{SNR} \approx \frac{\Delta R/R_0}{1/R_0} \approx \Delta R$$

The optimum sensitivity is therefore achieved where the absolute reflectivity change  $\Delta R$  rather than the relative peak intensity  $\Delta R/R_0$  is largest. Since  $\Delta R$  depends strongly on the type of substrate and on the incidence angle, an optimum angle  $\theta_{\text{opt}}$  exists for each substrate, where the best SNR is achieved. **Table 1** lists calculated  $\theta_{\text{opt}}$  values and corresponding relative SNRs for a number of common substrate materials. Whereas the optimum angle for p-polarized light lies between  $70^\circ$  and  $87^\circ$  for most substrates, the predicted SNR values differ largely and are generally 1–2 orders of magnitude lower than the

**Figure 4** Instrumental setup for reflection absorption infrared measurements.

**Table 1** Optimum incidence angles and relative signal-to-noise ratios (SNR) for external reflection infrared spectroscopy with different substrate materials using p-polarized light

Substrate	$\theta_{\text{opt}} (^\circ)$	SNR
Gold	87	100
Graphite	72	6
Silicon	86	2
ZnSe	84	0.6

SNR on a metal substrate. However, the use of a highly sensitive IR detector can compensate for most of these inherent sensitivity differences, as will be discussed below, and usually allows high-quality spectra in the monolayer coverage regime to be obtained on almost any type of substrate material.

**Detector** RAIRS is a typical low-light application (high throughput losses because of limited sample size and/or low substrate reflectivity) and therefore the most sensitive detectors will generally give the best results. The specific detectivity  $D^*$  as a measure of detector sensitivity ( $D^* = A^{1/2}/\text{NEP}$ , where  $A$  is the detector area ( $\text{cm}^2$ ) and NEP the noise equivalent power ( $\text{W Hz}^{-1/2}$ )) and the desired wavenumber range will be the main criteria for choosing the optimum detector. The most commonly used detectors are liquid nitrogen cooled semiconductors of the photoconductive type such as narrow-band mercury-cadmium-telluride ( $D^* \approx 5 \times 10^{10} \text{ cm Hz}^{1/2} \text{ W}^{-1}$ ,  $\Delta\nu = 5000\text{--}800 \text{ cm}^{-1}$ ) or of the photovoltaic type such as indium antimonide ( $D^* \approx 2 \times 10^{11}$ ,  $\Delta\nu = 10\,000\text{--}2000 \text{ cm}^{-1}$ ). In the far-IR region liquid helium cooled doped germanium or silicon bolometers ( $D^* \approx 5 \times 10^{10}$ ,  $\Delta\nu = 5000\text{--}200 \text{ cm}^{-1}$ ) are often used.

### Signal Processing and Sensitivity Optimization

In the conventional single beam operation a spectrum of the adsorbate-covered substrate is ratioed against a spectrum of the clean substrate to yield the reflection absorption spectrum of the adsorbate. For weakly reflecting nonmetallic substrates and/or small sample sizes only a small fraction of the source intensity reaches the detector and the SNR will be limited by detector noise. The use of a more sensitive detector and longer signal averaging are the only ways to improve the sensitivity. With highly reflecting substrates such as metals, however, the signal intensity at the detector often exceeds the dynamic range of the analog-to-digital converter and the SNR of a single-beam experiment will be limited by digitization noise. Several ways of circumventing this limitation have been proposed, aiming at a suppression of the centerburst in the interferogram by measuring only a difference signal proportional to the amount of light absorbed by the sample. One approach classified as dual-beam spectrometry is based on optical subtraction of the transmitted and reflected beams in the interferometer, which are  $180^\circ$  out of phase and whose modulated components cancel upon recombination. This can be realized experimentally by using either two input beams from two light sources or two output beams that are recombined

after passing through the interferometer. If the sample is placed in one of the two beams, only a difference signal proportional to the light absorbed by the sample is detected. This small signal can then be amplified until detector noise appears in the interferogram. The amplification factor corresponds directly to the SNR improvement over a single-beam experiment. An alternative method of reducing the dynamic range of the signal is polarization-modulation (PM-RAIRS), which is based on the same principle of measuring a difference signal from a sample that discriminates between two different states of polarization. A conventional single-beam optical system can be used together with a photoelastic modulator, which changes the polarization of the incident radiation from parallel to perpendicular at frequencies  $\sim 100 \text{ kHz}$ . A lock-in amplifier connected to the detector output and tuned to the polarization modulation frequency is used to obtain the difference signal between s- and p-polarized radiations.

## Applications

### Single Crystal Surfaces

RAIRS is widely used in combination with other surface science techniques to study adsorption and surface reactions on single crystal surfaces in an ultrahigh vacuum (UHV) environment. The vast majority of these studies have been carried out with strongly absorbing model compounds such as CO or NO and detection limits below 1% of a monolayer coverage have been achieved on metal surfaces. Recently, the focus of these investigations has shifted to practically more relevant systems owing to the increased sensitivity of modern FTIR instruments. The surface reactivity of simple hydrocarbon species, for example, has been monitored IR-spectroscopically on various catalytically important metal substrates. Molecular orientations of the adsorbed species have been determined based on the surface selection rules and related to their surface reactivity. **Figure 5** shows an example of the thermal decomposition of ethylene and ethyl iodide on a Pt(111) surface. Adsorption of ethylene at 100 K results in molecular chemisorption with the C–C bond axis parallel to the surface. Only a weak CH stretching band at  $2900 \text{ cm}^{-1}$  can be detected in the IR spectrum. At 300 K ethylene decomposes to form ethynylidyne ( $\text{CH}_3\text{C}\equiv$ ). Three absorptions at 2883, 1339, and  $1118 \text{ cm}^{-1}$  are observed and assigned to  $\nu_s(\text{CH}_3)$ ,  $\delta_s(\text{CH}_3)$ , and  $\nu(\text{CC})$ , all of which have a transition dipole moment parallel to the C–C bond. Since no other absorptions with different dipole moment orientations are detected, the C–C axis of ethynylidyne must stand

**Figure 5** RAIRS spectra of ethylene ( $\text{C}_2\text{H}_4$ ) chemisorbed at 100 K, ethylene chemisorbed at 300 K, and ethyl iodide ( $\text{C}_2\text{H}_5\text{I}$ ) chemisorbed at 300 K on a Pt(111) single crystal surface. (Reprinted with permission from Hoffmann H, Griffiths PR, and Zaera F (1992) A RAIRS study on the surface chemistry of ethyl iodide on Pt(111). *Surface Science* 262: 141–150; © Elsevier.)

perpendicular to the surface. Ethylidyne is also produced in the same adsorption geometry but with a lower surface concentration by adsorbing ethyl iodide at 300 K. This latter decomposition can be followed in the IR spectra at lower temperatures (100–300 K) and proceeds via the formation of ethyl radicals as stable intermediates on the surface. Alkyl radicals are known to be key intermediates in various industrial catalytic hydrocarbon reactions. They can be identified by RAIRS among other hydrocarbon fragments owing to the high resolution of IR spectroscopy.

A severe limitation for practical applications is the large pressure difference between single crystal experiments under UHV conditions and the real reaction conditions of heterogeneous catalysis and other surface processes. Most surface science techniques are restricted to pressures below  $10^{-6}$  Torr because they require hot filaments and high mean free paths for the probing particles. IR spectroscopy as an optical technique can be used in normal atmosphere as well as with liquid surroundings and is therefore ideally suited for *in situ* studies of surface processes under real reaction conditions.

### Thin Film Studies

Ordered monolayers of organic compounds, which can be prepared using the Langmuir-Blodgett or molecular self-assembly technique, have received growing attention both as model systems for synthetic organic interfaces and as technological products such

**Figure 6** Calculated (above) and experimental (below) RAIRS spectra for a methyl-16-mercaptohexadecanoate ( $\text{HS}(\text{CH}_2)_{15}\text{COOCH}_3$ ) monolayer on a gold surface. (Reprinted with permission from Nuzzo RG, Dubois LH, and Allara DL (1990) Fundamental studies of microscopic wetting on organic surfaces. *Journal of the American Chemical Society* 112: 558–569; © American Chemical Society.)

as nonlinear optical devices, chemically modified electrodes, lubrication layers, or synthetic membranes. Most of these applications are based on the densely packed, highly ordered structure of these monolayers, resulting from van der Waals interactions between the film molecule's hydrocarbon chains. Due to its nondestructive character RAIRS is one of the few surface analytical techniques that can provide quantitative information on the chemical composition and structure of these films. **Figure 6** shows an example of experimental and calculated spectra for a monolayer of  $\omega$ -mercapto-methylhexadecanoate ( $\text{HS}-(\text{CH}_2)_{15}-\text{COOCH}_3$ ) adsorbed on a gold substrate. The film molecules are bonded to the surface through their thiol end-groups and form a well-ordered monolayer film, whose interface to the ambient consists of the terminal ester groups. The sharp and intense bands in the IR spectrum reflect the densely packed, crystalline-like state of the adsorbate. The orientation of the film molecules on the surface can be obtained by comparing the experimental spectrum to a calculated spectrum of a monolayer film with isotropic molecule orientation. According to the surface selection rule the ratio  $I_{\text{obs}}/I_{\text{calc}}$  is proportional to  $\cos^2 \alpha$  for each vibrational mode, where  $I_{\text{obs}}$  and  $I_{\text{calc}}$  are the observed and calculated peak intensities, and  $\alpha$  is the angle

between the surface normal and the transition dipole moment of the vibration. For the example shown in **Figure 6**, a  $34^\circ$  tilt of the molecule axis toward the surface normal and a  $55^\circ$  twist of the C-atom plane from a configuration perpendicular to the surface has been derived from the  $\nu(\text{CH}_2)$  absorptions at  $2918$  and  $2850\text{ cm}^{-1}$ .

Recently, studies of monolayer film structure and composition have also been extended to nonmetal substrates, which have long been considered as unsuitable for RAIRS measurements due to their inherent low reflectivity and the often very complex band shapes of the film absorptions (see **Figure 3B**). In addition, the partial transparency of nonmetallic substrates also allows other surface techniques such as transmission or ATR spectroscopy to be used. The main advantages of RAIRS, on the other hand, are:

1. RAIRS requires no special sample geometry; it is based on a simple optical configuration and can therefore be used as an *in situ* technique for many surface processes.
2. RAIRS spectra are not affected by substrate absorptions that often block certain spectral regions in transmission and ATR spectra.
3. The complex band profiles of RAIRS spectra on nonmetal substrates contain highly specific information and allow—in combination with spectral simulations—a very detailed analysis of the film structure and composition.

An example of the unique sensitivity of RAIRS with nonmetals toward changes of the adsorbate structure is shown in **Figure 7**, where the formation of a monolayer film of octadecylsiloxane (ODS,  $\text{C}_{18}\text{H}_{37}\text{SiO}_x$ ) is monitored by RAIRS. Initially, the film molecules adsorb in a disordered, liquid-like configuration giving rise to 'negative' absorptions (pointing downward in an absorbance spectrum in accordance with an isotropic  $54.7^\circ$  dipole moment tilt angle, see **Figure 3C**) at  $2858\text{ cm}^{-1}$  ( $\nu_s(\text{CH}_2)$ ),  $2928\text{ cm}^{-1}$  ( $\nu_{as}(\text{CH}_2)$ ), and  $2960\text{ cm}^{-1}$  ( $\nu_{as}(\text{CH}_3)$ ). In the course of the monolayer formation process, the negative  $\nu(\text{CH}_2)$  absorptions are successively converted into positive peaks at lower wavenumbers ( $2850$  and  $2918\text{ cm}^{-1}$ ), indicating the formation of ordered film domains with vertically aligned hydrocarbon chains (dipole tilt angle  $0$ – $10^\circ$ ) to yield the final and highly characteristic spectrum of an ordered, densely packed ODS monolayer with sharp positive  $\nu(\text{CH}_2)$  peaks at  $2950$  and  $2918\text{ cm}^{-1}$  and negative  $\nu(\text{CH}_3)$  peaks at  $2878$  and  $2968\text{ cm}^{-1}$ . The same process on a metal substrate would lead to only minor band shifts and would be much harder to identify and to analyze than on silicon, where the

**Figure 7** RAIRS spectra in the CH stretching region monitoring the growth of an octadecylsiloxane monolayer on silicon.

disorder–order transition is associated with band inversions.

### Spectroelectrochemistry

IR-spectroscopic *in situ* studies of electrochemical processes at the electrode/electrolyte interface have recently gained great importance. The identity of reaction intermediates as well as their orientation and bonding on the electrode surface as a function of the electrode potential can be determined from RAIRS spectra. Besides the weak signal intensity of the adsorbed species, the strong absorption of the electrolyte imposes an additional problem that can be overcome by a special design of the electrochemical cell and the application of signal modulation techniques. Minimization of light absorption by the electrolyte requires the use of thin layer cells with a thickness of a few micrometers. The resulting drawbacks in the electrochemical behavior of these cells are a high ohmic resistance across the electrolyte film, a slow response to potential changes, and a hindered diffusion of reactants, which limit their application to low current processes. To eliminate the absorption of the bulk electrolyte solution several signal modulation techniques have been developed, among which PM-RAIRS and subtractively normalized interfacial FTIR spectroscopy (SNIFTIRS) are

most commonly used in conjunction with FTIR spectrometers. PM-RAIRS has been described earlier as a centerburst suppression technique, yielding a difference spectrum  $R_p - R_s$  between the reflectances of s- and p-polarized radiation. In an electrochemical cell a surface layer of  $\sim 1 \mu\text{m}$  thickness is probed with this technique and absorptions of the bulk electrolyte are eliminated by dividing two spectra taken at different electrode potentials. The SNIFTIRS method is based on a modulation of the electrode potential and yields a difference spectrum  $R^S - R^0$  between the reflectances at the sample and the reference potential. A square wave potential modulation with frequencies  $\sim 100 \text{ mHz}$  is usually employed allowing repeated co-addition of interferograms at each potential step until an acceptable SNR is achieved.

Figure 8 shows an example of a SNIFTIRS study of the electrochemical oxidation of 2,5-dihydroxythiophenol (DHT) on a gold electrode surface according to Scheme 1.

The spectra in Figure 8 were taken at different sample potentials between 0.1 and 0.6 V and were normalized to the reference potential of 0.1 V. Downward-pointing peaks correspond to a loss in starting material DHT and upward-pointing peaks to a gain in reaction products. The most prominent loss features are assigned to the C–O stretching ( $1207$ ,  $1180 \text{ cm}^{-1}$ ), the in-plane OH deformation ( $1342 \text{ cm}^{-1}$ ), and the aromatic CC stretching mode ( $1595 \text{ cm}^{-1}$ ) of DHT. The positive absorptions correspond to the C=O stretching ( $1647 \text{ cm}^{-1}$ ), the C=C stretching ( $1531$ ,  $1561 \text{ cm}^{-1}$ ), and the C–C stretching vibration ( $1286$ ,  $1306 \text{ cm}^{-1}$ ) of the oxidized benzochinonethiol. All these vibrations have a transition dipole moment parallel to the molecular plane. Their relatively large intensity provides evidence that both species are adsorbed with the molecular plane close to normal to the surface.

### Liquid Surfaces and Buried Interfaces

IR surface analysis is not restricted to solid/gas or solid/liquid interfaces, but can also be used to investigate liquid substrate surfaces (liquid/gas interfaces) and even solid/solid interfaces buried in the bulk of a solid sample. Even though the experimental setup and the measurements of such samples are fairly complex and far from a routine analytical technique, two examples shall be described here in order to show the potential and the diversity of IR spectroscopy in the field of surface analysis. In both cases, an experimental setup equal or similar to RAIRS is used with the light incidence angle being the only variable that must be adapted to the specific requirements of the sample system. In the first

**Figure 8** SNIFTIRS spectra of 2,5-dihydroxythiophenol adsorbed on a gold electrode at different electrode potentials and normalized to a 0.1 V reference potential: 0.2 V (A), 0.4 V (B), 0.5 V (C), 0.6 V (D), 0.4 V (E), and 0.1 V (F). (Reprinted with permission from Sasaki T, Bae IT, Scherson DA, Bravo BG, and Soriaga MP (1990) Oxidation-state changes of molecules irreversibly adsorbed on electrode surfaces as monitored by *in situ* Fourier transform infrared reflection absorption spectroscopy. *Langmuir* 6: 1234–1237; © American Chemical Society.)

**Scheme 1**

example, the goal is to detect and analyze an adsorbate layer formed at the surface of water in contact with air. Ordered monolayer films of water-insoluble compounds can be formed on a water surface via the Langmuir–Blodgett technique, where the film molecules are first spread onto the water subphase in a so-called Langmuir trough and are then compressed with the film balance and thereby forced into a densely packed, uniform orientation. The IR beam is focused onto the water surface just like with

a solid substrate, whereby the highest sensitivity is generally achieved with p-polarized light and an incidence angle close to the water's Brewster angle ( $53^\circ$ ). A typical instrumental setup is shown schematically in **Figure 9**, where the Langmuir trough is moved via a computer-controlled shuttle system between the sample position (compressed monolayer film) and the reference position (bare water subphase). Note that the sample surface in **Figure 9** is oriented horizontally and the light incidence plane lies vertically, opposite to the conventional RAIRS setup shown in **Figure 4**. **Figure 10** shows a series of spectra of a behenic acid methyl ester ( $\text{C}_{21}\text{H}_{43}\text{COOCH}_3$ ) monolayer on  $\text{D}_2\text{O}$ , measured with s-polarized and p-polarized light at different angles of incidence. The ester carbonyl band is observed at  $1737\text{ cm}^{-1}$  with a shoulder at  $1720\text{ cm}^{-1}$ , indicating that most of the carbonyl groups are monomeric and uncoordinated (main peak at  $1737\text{ cm}^{-1}$ ) whereas only a small fraction is H-bonded to the water subphase. The  $\text{CH}_2$  scissor vibration near  $1465\text{ cm}^{-1}$  is split into two components, which is a highly characteristic indication for an orthorhombic subcell structure of the hydrocarbon chains with an all-*trans* chain orientation normal to the water surface.

An even more challenging task is the investigation of solid/solid interfaces, which are ubiquitous in any

object containing welded, soldered, or glued parts. IR spectroscopy is one of the few analytical techniques that can not only penetrate to a solid/solid interface within a bulk solid sample, but can also provide a unique sensitivity enhancement up to monolayer sensitivity at such interfaces. A special sampling technique termed multiple internal transmission (MIT) has been developed originally to investigate a bonding method known as silicon wafer bonding, where two silicon surfaces are activated and brought into close contact, upon which a spontaneous bonding reaction takes place to form a covalent linkage between the two wafers. The optical lightpath through the sample in such an MIT experiment is shown in **Figure 11** and is reminiscent of the ATR technique, the difference being that MIT probes the interface layer not by the evanescent wave, but by the primary light beam that tunnels through the solid/solid interface and carries on the spectral information of the interface region. The best sensitivity is achieved for high incidence angles (large  $\theta$ ), where

**Figure 11** Light path of the IR beam within a bonded silicon wafer pair used in the multiple internal transmission method. The IR radiation is totally reflected at the outer Si/air surfaces and tunnels repeatedly through the bonding interface.

the perpendicular vibrational components at the interface are enhanced by several orders of magnitude compared to a standard transmission measurement. Thus, the optical setup and the surface selection rules are essentially identical to the RAIRS method with metal substrates. **Figure 12** shows the changes in the  $\nu(\text{SiO})$  and in the  $\nu(\text{OH})$  spectral regions of MIT spectra monitoring the bonding process as a function of the annealing temperature. The  $\nu(\text{SiO})$  absorption continuously increases and shifts to higher frequencies, indicating a thickness increase of the native surface oxide layers at the bonding interface. Concomitantly, the broad  $\nu(\text{OH})$  band at  $3500\text{ cm}^{-1}$  decreases, transforms into a sharp single absorption at  $3740\text{ cm}^{-1}$  at  $600^\circ\text{C}$ , reappears as a broad intense band at  $800^\circ\text{C}$ , and completely disappears at  $1000^\circ\text{C}$ . Based on these spectral observations, a bonding mechanism shown schematically in **Figure 13** has been proposed based on the following reaction sequence: at temperatures  $< 400^\circ\text{C}$ , the water molecules trapped at the interface diffuse through the oxide layers and form additional oxide at the Si/SiO<sub>2</sub> interface; the oxide thickness increases and the surface hydroxyl groups come into intimate contact. Between 400 and  $800^\circ\text{C}$ , a condensation reaction takes place between the interfacial hydroxyl groups resulting in Si–O–Si linkages between the two wafers and the formation of water, as indicated in the IR spectra by the reappearance of the  $\nu(\text{OH})$  water absorptions at  $800^\circ\text{C}$  and the growth of a characteristic Si–O–Si absorption at unusually high frequency due to the strained geometry of the bridging Si–O–Si bonds. Finally, between 800 and  $1200^\circ\text{C}$ , a combination of viscous flow in the oxide layer and elastic wafer deformations leads to complete closure of the interface under attainment of the ultimate bonding strength of a bulk quartz crystal.

### Surface Enhanced Infrared Absorption

The surface enhanced infrared absorption (SEIRA) effect, which is closely related to the better known surface enhanced Raman (SERS) effect, was

**Figure 12** MIT-IR spectra in the  $\nu(\text{SiO})$  region (A) and in the  $\nu(\text{OH})$  region (B) of the interface between two silicon wafers as a function of the annealing temperature. An optical setup as in **Figure 10** with an incidence angle of  $60^\circ$  and six internal passes was used. The shaded area indicates a region of intense substrate absorption. (Reprinted with permission from Weldon MK, Marsico VE, Chabal YJ, *et al.* (1996) Infrared spectroscopy as a probe of fundamental processes in microelectronics: silicon wafer cleaning and bonding. *Surface Science* 368: 163–178; © Elsevier.)

**Figure 13** Schematic bonding process of two native silicon wafers upon heating to  $1200^\circ\text{C}$ .

discovered more than 20 years ago but has been experimentally exploited primarily within the last decade. It is based on the phenomenon that an adsorbate deposited onto a microscopically rough metal substrate experiences an enhancement of its vibrational modes up to three orders of magnitude as compared to the same adsorbate on a flat substrate. The theoretical origin of this effect is still not completely

understood, yet it is widely used today as sensitivity amplifier in trace analysis, biosensing, catalysis, electrochemistry, time-resolved spectroscopy, etc. Properly prepared samples usually consist of an IR-transparent substrate ( $\text{CaF}_2$ ,  $\text{KBr}$ ,  $\text{ZnSe}$ ,  $\text{Si}$ ) onto which a SEIRA-active metal (usually  $\text{Ag}$ ,  $\text{Au}$ ,  $\text{Cu}$ ,  $\text{Pt}$ ) is deposited with strict control over thickness and morphology (shape, size, and density of the metal islands). Subsequently, the analyte is adsorbed onto this substrate and measured by either transmission, internal reflection (ATR), or external reflection (RAIRS). The obtained SEIRA spectra are usually not only more intense than the unenhanced reference spectra, but show very different relative band intensities and sometimes also bipolar or inverted absorptions, which initially increase very strongly with the adsorbed amount of analyte but level off at adsorbate thicknesses of a few nanometers. These results indicate that the enhancement is a truly local surface effect restricted to the first few layers of an adsorbate. If a surface process to be investigated is reversible, the sensitivity enhancement provided by SEIRA can be used to obtain time-resolved spectra with submicrosecond time resolution using step-scan FTIR. An example is shown in Figure 14, where the adsorption and desorption of fumaric acid ( $\text{HOOC}-\text{CH}=\text{CH}-\text{COOH}$ ) on a gold electrode, triggered by a square-wave potential modulation of the Au substrate, is monitored at  $100\text{ }\mu\text{s}$  intervals. Two major absorptions grow and disappear in Figure 14 synchronously, the carbonyl vibration  $\nu(\text{C}=\text{O})$  at  $1720\text{ cm}^{-1}$  and the symmetric carboxylate vibration  $\nu_s(\text{COO}^-)$  at  $1380\text{ cm}^{-1}$ . The concurrent presence of both bands indicates that fumaric acid bonds to the surface by adsorption and deprotonation of one carboxylic group, whereas the other  $\text{COOH}$  group is left intact and points away from the surface.

**Figure 14** Surface-enhanced time-resolved IR reflection spectra monitoring the adsorption and desorption of fumaric acid on a gold electrode. ## Trends

Despite being in use for over a 100 years, IR spectroscopy still experiences new and exciting developments, which steadily enlarge the range of applications and the types of samples to be studied. This applies, in particular, for IR surface spectroscopy, where several complete new branches of IR spectroscopy developed over the past 20 years for bulk samples have recently been adapted and applied to surface probes. One of them is time-resolved spectroscopy, which has been pushed down to the femtosecond range for conventional, transmission-type experiments with bulk samples utilizing pulsed light sources and ultrafast detectors. Obvious applications of time-resolved studies in surface science are the dynamics of surface reactions and surface diffusion, the monitoring of film growth processes such as chemical vapor deposition or mechanistic studies of surface-catalyzed reactions, characterization of transient species, etc., to name a few. Time resolutions of a few microseconds have recently been achieved with powdered, high surface area samples using step-scan FTIR. On single crystals and other low surface area supports with intrinsically lower SNRs, sampling times in the tenths of a second range are still required for covering a broader spectral range with FT-based techniques. Certain laser-based IR methods, on the other hand, such as sum frequency generation, allow time resolution down to femtoseconds, but their drawbacks are a limited spectral range (typically  $<100\text{ cm}^{-1}$ ) and a complex and expensive instrumentation. This gap between FT and laser-based techniques in terms of time resolution, spectral range, and equipment costs is getting narrower by steady advances on both sides. Another closely related goal in IR surface spectroscopy, imposed by new scientific branches such as nanoscience and nanotechnology, is the increase in spatial resolution, i.e., the ability to probe very small areas of a sample surface or to obtain an IR image of a surface with high spatial resolution, thereby combining spectral information with sample visualization. Based on the transmission IR microscope developed in the 1980s, their beam condensing and magnifying optics have been combined with various surface IR techniques such as ATR, RAIRS, or DRIFT and are now commercially available as surface IR microscopes for a wide range of solid, plane-surface, or powdered samples. As with any optical technique, the spatial resolution is determined by the diffraction limit and lies for surface probes in the mid-IR typically  $\sim 10\text{ }\mu\text{m}$ . Two major, recent developments in this area, which will be one of the main topics of surface analysis with IR in the next decade, can only be briefly mentioned here: near-field vibrational spectroscopy, which makes use of the fact that

an aperture or scattering center of subwavelength dimensions creates in its immediate neighborhood ('near field') an electric field with submicron wavelengths, which can be used to image objects with submicron resolution, and, secondly, IR imaging utilizing focal plane array (FPA) detectors, which will especially benefit in the upcoming years from their recent declassification by the US Department of Defense and the immense effort and funding currently channeled into IR detector technology. Even a combination of the latter two technologies, a near-field vibrational image of a surface obtained with an FPA detector in a few seconds with nanometer resolution is no longer unthinkable and might eventually provide instant chemical information of surfaces with a lateral resolution in the nanometer range.

## Introduction

Some chemical compounds such as surfactants are linked to the technological development of human communities. The use of the first known surfactant, soap, has been documented in Sumerian civilization back to ~2500 BC. The first synthetic surfactant, sodium lauryl sulfate (SLS) was synthesized in the laboratory by Dumas and Peligot in 1830; however, until the next century there was lack of necessary technology for industrial-scale production. A wide range of surfactant and commercial applications emerged after the Second World War with the development of petrochemistry, and it caused a change of hygienic–sanitary customs.

Surfactants are a group of organic compounds achieved by chemical synthesis and characterized for specific behavior in solution that makes them especially suitable for many human activities. Surfactant is an abbreviation for a surface-active agent that refers to its ability to reduce the interfacial tension between two phases (liquid–liquid, liquid–solid, and liquid–gaseous). This behavior is caused by the molecular composition in the surfactant, which has a hydrophobic part, composed of alkyl chains, and another part that is an ionic or hydrophilic group.

Detergents are chemical formulations made up of principal (surfactant) and complementary components. The latter may act to enhance the performance (builders, alkalis, complexing agents, ion exchangers, enzymes, antiredeposition agents, foaming stabilizers, whitener or optical brightener, viscosity improver, conditioner or softener, corrosion inhibitor, solvents) and enhancing the appearance (perfumes, dyes, opacifier). The number and type of complementary components depend on further use of formulation: clean fabrics, hard surface, or body.

## Introduction

Some chemical compounds such as surfactants are linked to the technological development of human communities. The use of the first known surfactant, soap, has been documented in Sumerian civilization back to ~2500 BC. The first synthetic surfactant, sodium lauryl sulfate (SLS) was synthesized in the laboratory by Dumas and Peligot in 1830; however, until the next century there was lack of necessary technology for industrial-scale production. A wide range of surfactant and commercial applications emerged after the Second World War with the development of petrochemistry, and it caused a change of hygienic–sanitary customs.

Surfactants are a group of organic compounds achieved by chemical synthesis and characterized for specific behavior in solution that makes them especially suitable for many human activities. Surfactant is an abbreviation for a surface-active agent that refers to its ability to reduce the interfacial tension between two phases (liquid–liquid, liquid–solid, and liquid–gaseous). This behavior is caused by the molecular composition in the surfactant, which has a hydrophobic part, composed of alkyl chains, and another part that is an ionic or hydrophilic group.

Detergents are chemical formulations made up of principal (surfactant) and complementary components. The latter may act to enhance the performance (builders, alkalis, complexing agents, ion exchangers, enzymes, antiredeposition agents, foaming stabilizers, whitener or optical brightener, viscosity improver, conditioner or softener, corrosion inhibitor, solvents) and enhancing the appearance (perfumes, dyes, opacifier). The number and type of complementary components depend on further use of formulation: clean fabrics, hard surface, or body.

Surfactants not only have detergency functions, but also other functions in formulation (softener, opacifier, conditioner, foam booster).

The most common classification of surfactants is based on the criterion of ionic group charge: there are anionic, cationic, nonionic, and amphoteric surfactants (Table 1). The anionic surfactants are primary surfactants that represent the principal detergent basis of formulations and a greater production of surfactants (millions of tons). The nonionic surfactants are the second group for amount of production and are used as emulsifiers and humectants. The property of cationic surfactants to adsorb on a surface makes possible their application as a softener, conditioner, and disinfectant. The amphoteric surfactants are compounds used frequently in cosmetics as detergents because they are less irritating and aggressive than anionic surfactants.

The analytical methodologies of surfactants and detergents are published by national organizations. To mention some of them, the British Standards Institute, BSI (London), Association Française of Normalisation Tour Europe, AFNOR (Paris), the Deutsches Institut für Normung, DIN (Berlin), The American Society for Testing Materials, ASTM (Philadelphia), and the Japanese Industrial Standards Committee, JISC (Tokyo). Information relating to standard methodologies accepted by national organizations might be obtained through the International Standards Organization (ISO).

The development of methods expanded with the appearance of new types and matrices of surfactant as well as new analytical techniques. Current trends include the study of environmental matrices, residual components, application of techniques such as capillary electrophoresis (CE) and combined techniques such as liquid chromatography and mass spectrometry (LC-MS).

This article discusses the state of the art of surfactant analyses taking into account classical methods and new approaches. Titrimetric and instrumental methods, analysis in two matrices (formulation and environmental), sample treatment, and qualitative and quantitative analysis will be examined.

## General Methods of Analysis

The analytical chemistry of surfactants presents some difficulty because most products contain a homologous chain and positional isomer in the hydrophobic part and may have an ethoxylated oligomer in the hydrophilic part. Also, they are compounds of low volatility with molecular weights above 200.

The titrimetric methods for determination of anionic and cationic surfactant concentrations are based on specific reactions between anionic and cationic surfactants in a two-phases system, chloroform-water, and with a transfer phase indicator for

**Table 1** Commonly used surfactants

	<i>Carboxylates</i>	<i>Sulfates</i>	<i>Sulfonates</i>
Anionics	Acyl sarcosinates Acylated peptides	Sulfated amides Alkyl sulfates Alkyl ether sulfates Sulfated alcohols Sulfated esters	Alkylbenzene sulfonates Dialkylsulfosuccinates Olefin and alkane sulfonates Sulfonates amides Sulfonated esters Sulfonates fatty esters Metal alkylphosphates Soaps
Cationics	Monoalkyl quaternary ammonium salts Dialkyl quaternary ammonium salts Amine oxides Imidazolinium derivatives Alkylamidoamines derivatives Alkylquinolinium and alkylisoquinolinium salts		Polymeric cationic Alkylpyridinium salts Alkylbenzylammonium salts Bis-quaternary ammonium derivatives Amines
Nonionics	Alcohols, ethoxylated Alkylphenols, ethoxylated Fatty alcohols Esters of polyhydric alcohols Esters of polyoxyalkylene glycols		Ethers of polyoxyalkylene glycols Dialkyl polyoxyalkylenephosphates Alkyl glycoside Polyoxyalkene oxide copolymers
Amphoterics	Carboxybetaines		Sulfobetaines

location of the endpoint. The most used indicator is a mixture of dimidium bromide and disulfine blue. Hyamine 1622 is used as titrant for anionic surfactant analysis and SLS for cationic surfactant analysis. This method is more sensitive than traditional titration and is quick and effective for quality control. A potentiometric titration using a surfactant-selective electrode is an alternative to two-phase titration that has advantages including a shorter analysis time and avoiding the use of a hazardous solvent such as chloroform.

Gas chromatography (GC) allows the distribution of the alkyl chain and ethoxylates to be ascertained but a sample treatment to convert surfactants into volatile compounds is necessary. Anionic surfactants with sulfonates and sulfates can be broken down by acid hydrolysis to yield alcohols. Derivatization using several agents is another way to achieve a volatile compound, for example, alkylaryl-, alpha olefin-, alkene-, and paraffinsulfonates can be converted to sulfonyl chlorides or methyl esters of alkyl sulfates (AS) to trimethylsilyl derivatives and linear alkylbenzenesulfonates (LAS) and AS to thiotrifluoroacetyl derivatives. Cationic surfactants of the alkyltrimethyl- and dialkyldimethylammonium type are thermally degraded to tertiary amines or by Hoffmann degradation to an olefin and alkylamine. Nonionic surfactants are treated by derivatization or cleavage, except for low molecular weight compounds that are analyzed directly. Alcohol ethoxylates (AE) and alkylphenol ethoxylates (APE) can be derivatized to form trimethylsilyl derivatives and acetate esters or fragmented in cleavage reactions with HBr, HI, or acetyl chloride.

LC provides information on the distribution of homologs and makes possible quantitative analysis of individual surfactants in mixtures without sample pretreatment. Three classes of aromatic surfactants (anionic as alkylarylsulfonates, cationic as alkylpyridinium and alkylbenzyltrimethylammonium, nonionic as APE) are analyzed using ultraviolet (UV) absorbance detection. A suitable alternative for nonaromatic surfactants such as alkenesulfonates, AS, or alkyltrimethylammonium is indirect detection with a mobile phase containing a UV-absorbing ion. Conductometric detection, combined with reversed-phase and ion chromatography, is used for analysis of all common anionic and nonaromatic cationic surfactants (alkyltrimethyl- and dialkyldimethylammonium). Simultaneous separation of an individual surfactant (alkylpyridinium, alkylbenzyltrimethyl-, and alkyltrimethylammonium) and its homologs may be achieved using a refractive index detector. Fluorescence detection is chosen for trace analysis of surfactants.

Reversed-phase LC, occasionally with paired ions, allows alkyl chain homologs to be separated from anionic and cationic surfactants, although for the latter, normal and reversed-phase LC on a cyano column is applicable. For nonionic surfactants, in general, reversed-phase LC using a C<sub>18</sub> column gives a separation on the basis of alkyl chain length and normal-phase chromatography according to the ethoxy chain distribution.

Automated chromatographic systems allow the determination of the ethoxy chain distribution and alkyl chain length by combining two separation methods for a nonionic surfactant. It is even possible to use two-dimensional chromatography under critical conditions (LCCC) and liquid exclusion-adsorption chromatography (LEAC). For example, separations are carried out for the alkyl chain in fatty AE by LCCC and the ethoxy chain by LEAC using refractive index detection (Figure 1).

CE is a separation technique that may be an alternative to LC to determine alkyl chain distribution of anionic and cationic surfactants. Most of the studies refer to alkylbenzyltrimethylammonium with UV absorbance detection (Figure 2). Other uses of CE include the separation of homologs of anionic surfactants (as AS) and cationic (as alkyltrimethylammonium) by isotachopheresis with conductometric detection and homologs of non-UV absorbing surfactants (AS, alkylsulfonate, alkylsarcosinates and dialkyldimethylammonium) by capillary zone electrophoresis using indirect detection.

Infrared (IR) spectroscopy and nuclear magnetic resonance (NMR) spectroscopy are two techniques of great relevance for the characterization of surfactants and their mixtures which are applied for quality control. The degree of branching of the alkyl chain in LAS can be measured by either of them. <sup>13</sup>C NMR has been utilized for determination of individual LAS isomers. Other examples of NMR applications include the measurement of the ratio of alkyl to ethoxy chain length in APE, to quantify mixtures of dialkyldimethyl and monoalkyltrimethylammonium, and to characterize alpha olefinsulfonates. Regarding IR spectroscopy, some applications focused on quality control are the determination of ethylene oxide content in ethoxylated surfactants or number average molecular weight by measurement of the hydroxyl groups.

MS is utilized for the characterization of structures and determination of molecular weight. The production of gaseous ions from surfactants is carried out using soft ionization techniques. The chosen technique depends on the surfactant but those frequently used are field desorption and fast atom bombardment

(FAB). The information of the molecular weight distribution of surfactant oligomers is provided by the parent ion spectrum. Other structural information include location of positions of unsaturation, isomer distribution, and degree of branching. The use of FAB-MS for anionic surfactant analysis makes possible the determination of chain length and branching as well as distinguishing between linear alkylbenzenesulfonates (ABS and LAS). In addition, it has been applied to ethoxylates and cationic surfactants analysis.

MS can be coupled with GC, LC, supercritical fluid chromatography, and MS (Figure 3). Most of the studies by MS have referred to commonly used surfactants such as LAS, APE, and alkylbenzyltrimethylammonium in environmental matrices.

## Analysis of Detergent Formulations and Other Formulated Products

The formulation class (tooth paste, shampoo, fabric softener, etc.) provides basic information about the components present. Standard shampoo formulations contain two types of surfactants (either two anionic or one anionic and one amphoteric surfactant); foam booster (nonionic surfactant); conditioner, viscosity improver, opacifier, dye, perfume, chelate, and preservatives. Normally, formulated products are available as liquid, solid, emulsion, dispersion, etc, with a great number of components (in some cosmetic products there may be 20 components) and some of them, such as the preservatives, are found at low concentrations.

**Figure 3** Separation of LAS alkyl chain isomers converted into thiotrifluoroacetates by GC-MS. (Reproduced (reprinted) with permission from *Rivista Italiana delle Sostanze Grasse* (2001), 78: 273–276.)

Initial examination generally starts with the determination of total solids, volatile matter, and water intended for mass balance calculations. The difference between the two later parameters is the content of organic solvent and perfumes. A general procedure consists of the following: from solids, the ethanol-soluble material (where surfactants are found) is separated from the insoluble material (containing inorganic compounds). Isolation of different classes of surfactants (anionic, cationic, amphoteric, and nonionic surfactants) from the organic fraction is realized by ion exchange, column and thin layer chromatography, and liquid–liquid extraction. Alternatives to classical methods, solid-phase extraction (SPE) and supercritical fluid extraction (SFE), reduce analysis time and solvent consumption. Solid-phase microextraction has demonstrated useful properties for sampling aqueous samples. The choice of separation mode depends, at least, on the type of required information, on the matrix, and available instrumentation.

IR is a nondestructive technique suitable for the analysis of formulated products, and gives a considerable amount of information about the compounds present. Near-infrared (from 13 000 to 4000  $\text{cm}^{-1}$ ) and Fourier transform infrared (FTIR) (from 4000 to 400  $\text{cm}^{-1}$ ) spectroscopies are used. Qualitative analysis of the ethanol soluble fraction allows the identification of functional group types such as hydrotropes (xylenesulfonate and toluenesulfonate). In addition, zeolite, alkalis, polymers, and builders may be identified in the insoluble ethanol fraction. For quantitative analysis, method development is slow because a great number of calibration standards

are necessary; however, sample analysis is achieved in a few minutes. Alkyl ether sulfate (AES) and fatty alkanolamide are quantified in shampoos by FTIR spectrometry with similar results obtained by two-phase titration. Also, powder soap, heavy-duty laundry detergent, and bar soap are analyzed by FTIR spectrometry using diffuse reflectance for solid samples.

Surfactants, hydrotropes, and sequestering agents are analyzed without sample pretreatment in liquid detergent by  $^{13}\text{C}$  NMR spectroscopy and phosphorus species present in detergents are quantified by  $^{31}\text{P}$  NMR spectrometry.

The analysis of solvent and perfumes in formulations is performed by GC. For solvent analysis in surfactants sample pretreatment with organic solvent is used for the separation of inorganic impurities. Regarding surfactants and complementary compounds, applications may be mentioned such as the separation of a hardness agent (sodium laurate) in liquid laundry detergent by GC and the Hofmann degradation and analyses of cationic surfactant of the alkyltrimethyl- and dialkyldimethylammonium type in fabric softener and hair rinse.

LC is a separation technique of great importance for formulations since it allows the quantification of a broad spectrum of compounds from surfactants to minor compounds in matrices of detergents, cosmetic products, and industrial products. LC using UV absorbance detection is used in the determination of anionic surfactants (alkylbenzene sulfonate) and nonionic surfactants (APE) in liquid pesticide formulations; cationic surfactants such as cetylpyridinium in pharmaceutical tablets; and benzalkonium

chloride in ophthalmic preparations. Nonchromophore surfactants are analyzed in cosmetic products (shampoos, foam bath, make-up remover lotion) by normal-phase and reversed-phase elution with short-wavelength UV detection. These compounds may be nonionic surfactants (alkanolamides), amphoteric surfactants (carboxybetaine and carboxyimidazoline), anionic surfactants (alkylsulfates, alkyl-ethoxysulfates, sarcosinate, and types of sulfonates such as taurate and sulfosuccinate). Examples of other detection modes are the determination of alkyltrimethylammonium (cationic surfactant) in skin moisture formulation using refractive index detection. Also, alkylsulfonates in shampoo and LAS in laundry detergent by LC with postcolumn addition of a solid-phase reagent followed by conductometric detection. The evaporative light-scattering detector is utilized for the determination of alkyl ether sulfates, synthetic and petroleum sulfonates, and AE in industrial formulated products.

Ion chromatography with inverse conductivity detection gives good results for the analysis of minor components such as buffering agents (triethanolamine, monoethanolamine, diethanolamine, and silicate) or an enzyme stabilizer (formate) in laundry detergent. Also, a sequestrant such as citrate may be determined in powdered and liquid laundry detergent by ion-exchange chromatography with UV absorbance detection. Other components, such as enzymes, can be quantified in detergent formulations by specific procedures involving measurement by plasma desorption, laser desorption, or ion-spray MS.

Inductively coupled plasma-atomic emission spectrometry allows the determination of anionic surfactants (LAS and AS) and inorganic compounds (phosphate, silicate, zeolite, sulfate). Other techniques, such as X-ray fluorescence spectroscopy and X-ray powder diffraction, have been used for the qualitative analysis of inorganic detergents. For surface analysis, optical light microscopy, scanning electron microscopy, and transmission electron microscopy characterize particles, deposition of surfactant, or other detergent ingredients on fabric.

Studies performed by MS on cosmetic products demonstrate the utility of this technique for analysis of hair-care surfactants. After sample pretreatment for the separation of different kinds of surfactant, the usual identification of anionic surfactant such as AE, AES, and less common surfactants (lauryl sulfosuccinate, *N*-acyl-*N*-methyl taurate, paraffin sulfonate) is possible. Amphoteric surfactants (cocoamidopropylbetaine) and those present less frequently (lauryl hydroxysultaine) have been identified by this technique as well. For other kinds of components

that are found in hair-care formulations, nonionic surfactants (AE and cocodiethanolamide, CDEA) and cationic surfactants (alkyltrimethylammonium and dialkyldimethylammonium), MS is a valuable technique.

The application of LC-MS achieves separation and identification of surfactants in formulated products. A representative example is the analysis of homologs of a cationic surfactant (ditallowdimethylammonium) and its impurities (tritallowmethylammonium) by normal-phase LC-MS FAB mode.

## Environmental Analysis

The analysis sequence for environmental matrices starts with sampling to provide a representative, sufficient, and well-preserved sample (refrigerator, formaldehyde, glass vessel, etc.). After a concentration step, isolation of other materials and cleanup with different techniques, depending on the matrix (liquid, liquid with particles, solid), is carried out. For aqueous matrices, liquid-liquid extraction with direct evaporation or solvent sublation when emulsions are formed and steam distillation (separation of nonylphenol from water) is used. Solid samples (sediment, sludge, etc.) are Soxhlet extracted. If class fractionation is required (for example, cationic or anionic surfactants), good results are obtained using SPE with ionic-exchange resins. SFE is used for specific problems when there is chemical breakdown in the extraction of solid materials (cationic compounds with ester group) and also for isolation of ionic and nonionic surfactants in sludge. SFE has advantages with respect to classical extraction techniques because it does not use hazardous solvents.

The purpose of analysis is to try and gain information on several aspects: total surfactant concentration, specific surfactant identity, or minor compound identity whose presence is linked to the use of detergent. For the first case, nonspecific methods such as colorimetric or indirect measurements such as degradation (CO<sub>2</sub> or total organic carbon) are enough. Colorimetric methods for cationic and anionic surfactants are based on two-phase extraction, of a complex formed between the surfactant and a colored reagent identified by spectrophotometric measurements. For anionic surfactants, the most common reagent is methylene blue; for cationic surfactants it is disulfine blue. The methods for nonionic surfactants are based on complex formation between the ethoxylated chain and a metal (Dragendorff reagent, ammonium thiocyanatecobaltate) and quantification by AAS or colorimetry. The

results of these methods are expressed as amount of disulfine blue active substance, methylene blue active substance, or cobalt active substance.

Instrumental techniques (HPLC, GC, CE, MS) are applied for the study of specific surfactants. GC, using desulfonation techniques, is used for LAS analysis in river water, sewage, superficial water, and sewage sludge. Also, biodegradation products of LAS are examined by this technique occasionally with MS detection. Homologs and isomers can be separated by LC, albeit with lower resolution. Normally, fluorescence detection is used when concentrations are at levels of submicrograms per liter in river water, treatment plants, and even seawater, sediment, and fish tissue. The first degradation products of LAS, sulfophenylcarboxylic acids, are analyzed in treatment plants as well. LC is available to separate alkyl chain LAS of nonionic surfactants as APE in reversed-phase using fluorescence detection.

Concerning nonionic surfactants, AEs are determined in surface and waste waters by GC after HBr cleavage. Homologs and oligomers of APE can be analyzed after derivatization using normal- and reversed-phase chromatography with fluorimetric detection at microgram per liter levels. Likewise, alkylphenoxycarboxylic acids have been determined by LC in studies of APE biodegradation. The latter may form halogenated by-products during disinfection treatment. LC-MS is employed for APE and halogenated APE analysis in sludge, river sediments, and surface, drinking, and waste waters (Figure 4).

Dialkyldimethylammonium surfactants and specifically DHTDMAC are the cationic surfactants most used, as fabric conditioners. DHTDMAC has been

studied by LC in a nonaqueous medium using conductometric detection at concentrations of submicrogram per liter levels in river water, sewage treatment, sludge, sediment, and soil. Another method applied to DHTDMAC in river water uses fluorescence or UV absorbance detection with a post-column detector system. Cationic surfactants are detected because these form ion-pairs with methyl orange or dimethoxyanthracene sulfonate, providing good detection limits.

Homologs of alkylbenzyltrimethylammonium, particularly benzalkonium chloride (BAK), used as disinfectants and bactericides can be determined at microgram per milliliter levels in effluents from hospitals by LC using postcolumn derivatization and fluorescence detection. Also, BAK was determined after sample treatment using SPE with LC-MS and LC-MS/MS detection in waste and river waters.

## Residual Components in Surfactants

Residual components in surfactants are undesirable because of their toxicity or inadequacy for the finished product, the result of side and unfinished reactions, mainly from raw materials, and the process. Metals at low concentrations may be encountered in surfactants. Some metals such as iron, nickel, and chromium originate mainly from corrosion of process plant materials; mercury comes from alkalis. Their detection is performed by three modes of AAS: flame AAS for iron determination in detergents; furnace AAS for chromium, nickel, and iron in powder

**Figure 4** Determination of an APE (nonylphenol ethoxylate) in sludge by LC-MS (TIC = total ion current). (Reprinted with permission from *Analytical Chemistry* (2000), 72: 4560–4567; © American Chemical Society.)

**Figure 5** LC separation of benzyl chloride during BAK synthesis. Peaks: 1 = benzyl alcohol, 2 = benzaldehyde, 3 = benzyl chloride, 4 = unidentified impurity, 5 = C<sub>12</sub> homolog, 6 = C<sub>14</sub> homolog, 7 = C<sub>16</sub> homolog. soap with high concentrations of phosphate; and cold vapor generation AAS for mercury.

Organic residual components are the most worrying because of their toxicity. Some of these compounds are formed as by-products. Volatile organic compounds are determined by headspace GC, GC-MS. Intermediate products, such as sultones and sulfones, from sulfonation of olefin and alkylbenzene, respectively, can be detected by LC. Unreacted products, like ethylene oxide from the synthesis of ethoxylated nonionic and anionic surfactants, are studied by GC; benzyl chloride from the quaternization of tertiary amines and aliphatic amines from amidation reaction are determined by LC (Figure 5).

N-Nitrosamines deserve special attention owing to their toxic and carcinogenic properties. They can be formed by nitrosation of secondary amines such as diethanolamine present in triethanolamine and coconut diethanolamide. Their analysis methods are diverse: colorimetric, polarographic, and chromatographic (GC, GC-MS, and LC).

# SWEETENERS

**M C Yebra-Biurrun**, University of Santiago de Compostela, Santiago de Compostela, Spain  
© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Sweeteners are defined as food additives that are used or intended to be used either to impart a sweet taste to food or as a tabletop sweetener. Tabletop sweeteners are products that consist of, or include, any permitted sweeteners and are intended for sale to the ultimate consumer, normally for use as an alternative to sugar. Foods with sweetening properties, such as sugar and honey, are not additives and are excluded from the scope of official regulations. Sweeteners are classified as either high intensity or bulk (**Figure 1**). High-intensity sweeteners possess a sweet taste, but are noncaloric, provide essentially no bulk to food, have greater sweetness than sugar, and are therefore used at very low levels. On the other hand, bulk sweeteners are generally carbohydrates, providing energy (calories) and bulk to food. These have a similar sweetness to sugar and are used at comparable levels.

## High-Intensity Sweeteners

High-intensity sweeteners (also called nonnutritive sweeteners) can offer consumers a way to enjoy the taste of sweetness with little or no energy intake or glycemic response and they do not support growth of oral cavity microorganisms. Therefore, they are principally aimed at consumers in four areas of the food and beverage markets: treatment of obesity, maintenance of body weight, management of diabetes, and prevention and reduction of dental caries. There are several different high-intensity sweeteners. Some of the sweeteners are naturally occurring, while others are synthetic (artificial) or semisynthetic. Most of the more commonly available high-intensity sweeteners and/or their metabolites are rapidly absorbed in the gastrointestinal tract. For example, acesulfame-K and saccharin are not metabolized and are excreted unchanged by the kidney. Sucralose, stevioside, and cyclamate undergo degrees of metabolism, and their metabolites are readily excreted.

Acesulfame-K, aspartame, and saccharin are permitted as intense sweeteners for use in food, virtually worldwide. In order to decrease cost and improve taste quality, high-intensity sweeteners are often used as mixtures of different, synergistically compatible

Sweeteners	High-intensity (non-nutritive)	Synthetic artificial	Acesulfame Alitame Aspartame Cyclamate		Neotame Saccharin Sucralose
		Semisynthetic	Neohesperidine dihydrochalcone		
		Natural	Glycyrrhizin Stevioside Thaumatococin		
	Bulk (nutritive)	Caloric	Sucrose Molasses Honey and maple syrup		
			Starch-derived sweeteners		Glucose Fructose
		Low-caloric	Sugar alcohols	Monosaccharides	Erythritol Mannitol Sorbitol Xylitol

Hydrogenated starch hydrolyzates (HSH)					
		Tagatose			

**Figure 1** Classification of sweeteners.

sweeteners. Sweetness characteristics of high-intensity sweeteners are shown in Table 1.

The more important properties of the high-intensity sweeteners that are permitted for use in food and drink applications are shown in Table 2.

### Acesulfame-K

Acesulfame-K [I] has an excellent stability under high temperatures, and good solubility which makes it suitable for numerous products. It is approved for use in food and beverage products in ~90 countries, including the USA, Switzerland, Norway, UK, Canada, Australia, and the European Union (EU).

Acesulfame-K

Systematic name: 6-methyl-1,2,3-oxathiazin-4(3H)-one-2,2-dioxide, potassium salt

### Alitame

Alitame [II] is nutritive, but due to its intense sweetness, the amounts used are small enough for it to be considered and classified as a non-nutritive sweetener. Alitame is formed from the amino acids L-aspartic acid and D-alanine with a novel amide moiety (formed from 2,2,4,4-tetramethylthienanylamine). Alitame exhibits superior stability under a variety of conditions because of its unique amide group. Alitame has been approved

for use in some countries such as Australia, Mexico, New Zealand, and China, but not in the USA or EU.

Alitame

Systematic name: L- $\alpha$ -aspartyl-N-(2,2,4,4-tetramethyl-3-thietanyl)-D-alaninamide

### Aspartame

Aspartame [III] is made from two amino acid components, L-aspartic acid and L-phenylalanine. Although nutritive, containing 4 kcal g<sup>-1</sup> like any other protein substance, due to its intense sweetness, the amounts used are small enough for aspartame to be considered and classified as a nonnutritive sweetener. In the dry form, the stability of aspartame is good and little decomposition is observed if the moisture content is kept below 8%. However, in solution, and under heat, it is not stable and undergoes hydrolysis to the free dipeptide and methanol, and cyclodehydration to its diketopiperazine derivative, in both cases with loss of sweetness. People suffering from the metabolic disorder phenylketonuria are unable to metabolize L-phenylalanine resulting from the hydrolysis of the dipeptide and are advised to avoid this sweetener. Hydrolysis of the ester functionality affords methanol but in insufficient quantities to be harmful. Aspartame is approved in more than 90 countries (the EU, the USA, Canada, South America, Australia, Japan, etc.) for use in numerous food-stuffs.

Aspartame

Systematic name: N-L- $\alpha$ -aspartyl-L-phenylalanine-1-methyl ester

**Table 1** Sweetness characteristics of high-intensity sweeteners (the scale uses sucrose as a sweetness of 1, and compares the sweetness of other sweeteners to sucrose)

Sweetener	Relative sweetness (sucrose = 1)	Aftertaste
Acesulfame-K	150–200	Very slight bitter
Alitame	2000–3000	Not unpleasant
Aspartame	160–220	Prolonged sweetness
Aspartame–acesulfame salt	350	–
Cyclamate	30–40	Prolonged sweetness. At high concentrations a distinct sweet–sour lingering
Glycyrrhizin	50–100	Prolonged sweetness (liquorice)
Neohesperidine dihydrochalcone	1000–2000	Lingering menthol–liquorice
Neotame	7000–13 000	Not unpleasant
Saccharin	300–600	Bitter metallic
Stevioside	250–300	Bitter and unpleasant
Sucralose	400–800	Not unpleasant
Thaumatococin	2000	Liquorice

### Aspartame–acesulfame salt

The salt is prepared by heating an ~2:1 ratio (w/w) of aspartame and acesulfame-K in solution at acidic pH. Aspartame–acesulfame dissolves completely in saliva and gastric juice. Although this salt it mainly consists of the two approved sweeteners, it is considered as a separate compound, which requires specific approval in certain countries. In the EU, it is part of the Proposed Amendment to the Sweeteners

**Table 2** Characteristics and selected physical properties of high-intensity sweeteners

Sweetener	Molecular formula	Molecular weight	m.p. (°C)	Solubility in H <sub>2</sub> O at 20°C (%)	ADI (mg per kg bodyweight)	
					JECFA	SCF

Directive expected to be adopted during 2004. It is approved in the USA, Canada, UK, Mexico, Russia, and China.

### Cyclamate

Cyclamate [IV] is generally used in the form of a sodium salt [V] because it is more soluble in water than the free acid. The calcium salt is also used as a sweetener, but, for some applications, it is not suitable as it can cause gelation and precipitation. Sodium cyclamate exhibits good stability in the solid form and is also stable in soft drink formulations within the pH range 2–10. Cyclamate is permitted in several countries (EU, Australia, Canada, New Zealand, etc.). However, it has been banned in the USA after controversial toxicity studies.

### Glycyrrhizin

Glycyrrhizin [VI] is a terpenoid glycoside and is isolated from the liquorice root plant *Glycyrrhiza*

*glabra* L. Glycyrrhizin as the ammonium salt is soluble in both hot and cold water and is stable in its dry form. Glycyrrhizin is used in Japan and in other countries as sweetening agent. In the USA, it is approved for use as a flavor and flavor enhancer.

### Neohesperidine dihydrochalcone

Neohesperidine dihydrochalcone [VII] is a semisynthetic sweetener prepared from neohesperidin or naringin, two flavanones extracted from citrus peel. In aqueous solutions, neohesperidine dihydrochalcone is stable in the pH range 2.5–3.5. Neohesperidine

dihydrochalcone is currently allowed for many applications within the EU. In the USA, it is approved for flavoring food products.

Neohesperidine dihydrochalcone  
Systematic name: 3,5-dihydroxy-4-(3-hydroxy-4-methoxy-hydrocinnamoyl)phenyl-2-O-(6-deoxy- $\alpha$ -L-mannopyranosyl)- $\beta$ -D-glucopyranoside

### Neotame

Neotame [VIII] is a derivative of the dipeptide composed of the amino acids aspartic acid and phenylalanine. The optimum pH for maximum stability is  $\sim 4.5$ . Neotame has been approved in the USA, Australia, and New Zealand.

Neotame  
Systematic name: L-phenylalanine, N-(3,3-dimethylbutyl)-L- $\alpha$ -aspartyl-2-methyl ester

### Saccharin

This is the oldest high-intensity sweetener. It is commercially available in three forms: acid saccharin [IX], sodium saccharin [X], and calcium saccharin. Sodium saccharin is the most commonly used form because of its high solubility and stability. Saccharin and its salts in their solid form show good stability under conditions present in soft drinks. However, at low pH they can slowly hydrolyze to 2-sulfobenzoic acid and 2-sulfamoylbenzoic acid. Saccharin continues to be used in food and drink formulations in at least 90 countries despite controversy over its safety. Many studies have shown that there is no significant risk of cancer in humans associated with consumption of large quantities of saccharin. However, in the USA, an accompanying warning label was required until 2000. In 2000, after more than 20 years of scientific studies and further research, legislation was

passed giving saccharin a clean bill of health and the warning label was allowed to be removed.

[IX]

Saccharin

Systematic name: 1,2-benzisothiazol-3(2H)-one-1,1-dioxide

[X]

Sodium saccharin

Systematic name: 1,2-benzisothiazol-3(2H)-one-1,1-dioxide, sodium salt

### Stevioside

Stevioside or stevia [XI] is the name given to a group of sweet diterpene glycosides extracted from the leaves of *Stevia Rebaudiana* plant (native of South America). Steviosides show good stability in the solid form. They are also quite stable in acidic condition beverages at 22°C. Steviosides are approved for food use in several South American and Asian countries, but lack approval in Europe and North America.

[XI]

Stevioside

Systematic name: 13-[(2-O- $\beta$ -D-glucopyranosyl- $\alpha$ -D-glucopyranosyl)oxy]-kaur-16-en-18-oic acid-4 $\alpha$ - $\beta$ -D-glucopyranosyl ester

## Sucralose

Sucralose [XII] is the common name for a sweetener derived from ordinary sugar through a multistep patented manufacturing process that selectively substitutes three atoms of chlorine for three hydroxyl groups on the sugar molecule. One advantage of sucralose for food and beverage manufacturers and consumers is its exceptional stability. Under forcing conditions in acidic solution it slowly hydrolyzes to its constituent chlorinated monosaccharides 4-chloro-4-deoxy-D-galactose and 1,6-dichloro-1,6-dideoxy-D-fructose. Following a lengthy safety evaluation it has been approved in the USA and in more than 35 countries around the world. In the EU, it is part of the Proposed Amendment to the Sweeteners Directive expected to be adopted during 2004.

[XII]

Sucralose

Systematic name: 1,6-dichloro-1,6-dideoxy- $\beta$ -D-fructofuranosyl  
4-chloro-4-deoxy- $\alpha$ -D-galactopyranoside

## Thaumatococcus

Thaumatococcus is a group of intensely sweet basic proteins isolated from the fruit of *Thaumatococcus danielli* (West African Katemfe fruit). It consists essentially of the proteins Thaumatococcus I and Thaumatococcus II. Thaumatococcus is a taste-modifying protein that functions as natural sweetener or flavor enhancer. Thaumatococcus is stable in aqueous solutions between pH 2.0 and 10 at room temperature. As occurs with aspartame it is nutritive, containing 4 kcal g<sup>-1</sup>, but due to its intense sweetness, the amounts used are small enough for thaumatococcus to be considered and classified as a nonnutritive sweetener. Thaumatococcus is approved for a number of uses in UK, Japan, Australia, the EU, and in many other countries. In the USA, it is approved as a flavor enhancer.

## Analytical Methodology

Nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS) are useful techniques for structural elucidation of unknown compounds but the results obtained are difficult to quantify. Liquid chromatography (LC) methods have been used extensively for the determination of highly intense sweeteners because in many instances the sample

matrices from which they are to be determined may be complex. In addition, a sweetener may be used in combination with other sweetener(s). Nevertheless, in recent years, capillary electrophoresis methods were developed that compete successfully with LC methodologies. Figure 2 shows the most common techniques used for the determination of high-intensity sweeteners, and it can be seen that LC is the most widely used technique for all, except for cyclamate. There are no methodologies proposed for the determination of neotame and only a few methods for alitame and thaumatococcus. Most methods for the determination of thaumatococcus involve immunochemical assays (IC) and measurement in an enzyme-linked immunosorbent assay reader. On the other hand, the largest number of methodologies has been proposed for the determination of saccharin because it is the oldest known and used high-intensity sweetener. Automated continuous determinations by flow injection analysis (FIA) have been developed for acesulfame-K, aspartame, cyclamate, and saccharin; generally, these procedures involve spectrophotometric and electro-analytical detections.

**Sample preparation** Sample preparation for the determination of high-intensity sweeteners is relatively simple. Carbonated soft drinks are degassed prior to analysis. Liquid beverages and tabletop sweeteners are diluted or dissolved in water. Sweeteners in complex foods are extracted with water or an appropriate solvent. Then, the extract can be clarified, centrifuged, or cleaned by using solid-phase extraction techniques.

**Liquid chromatography** LC using amino, ion-exchange, or reversed-phase columns allows the separation of a sweetener from other sweeteners and additives present in foods in a single chromatographic run. The mobile phase can be methanol-water, methanol-acetic acid, methanol-phosphate buffer, methanol-ammonium citrate, or acetonitrile-phosphate buffer, when reversed-phase columns (RP-C18) are used. Methanol-phosphoric acid and Na<sub>2</sub>CO<sub>3</sub> or NaOH solutions were used with amino and ion-exchange columns, respectively. Acesulfame-K, alitame, aspartame, glycyrrhizin, neohesperidine dihydrochalcone, saccharin, and stevioside can be determined by ultraviolet (UV) absorbance (192–282 nm), and by amperometric or conductimetric detection in the case of ion-chromatographic procedures. Aspartame can be detected by fluorimetry ( $\lambda_{\text{EX}} = 205$  nm,  $\lambda_{\text{EM}} = 284$  nm). Cyclamate and sucralose are poorly detected by UV absorbance due to the absence of a chromophore. These sweeteners can be detected by UV absorbance if converted

**Figure 2** Analytical methodologies for the determination of high-intensity sweeteners. NHDC, neohesperidine dihydrochalcone; LC, liquid chromatography; GC, gas chromatography; TLC, thin-layer chromatography; CE, capillary electrophoresis; SP, spectrophotometric; EA, electroanalytical; T, titrimetry; G, gravimetry; IC, immunochemical. Source of information: *Chemical Abstracts* (until January 2004).

into a derivative possessing strong UV absorption: sucralose by treatment with *p*-nitrobenzoyl chloride, and cyclamate by conversion to dichlorohexylamine for UV detection or to a fluorescence derivative for fluorimetric detection. An alternative for the determination of these sweeteners is the postcolumn ion-pair extraction where the eluted sweetener is mixed with an appropriate dye (methyl violet or crystal violet) being detected by visible absorption. Furthermore, sucralose and cyclamate can be detected directly by refractive index.

**Gas chromatography** Acesulfame-K, aspartame, cyclamate, saccharin, and stevioside are determined by gas chromatography, but the main drawback of this technique is that a derivatization is required. Acesulfame-K is methylated with ethereal diazomethane, aspartame is converted into its *N*-(2-methylpropoxycarbonyl) methyl ester derivative, menthol and isobutyl chloroformate are used to convert aspartame to 3-[(isobutoxycarbonyl)amino]-4-[[ $\alpha$ -(methoxycarbonyl)phenethyl]amino]-4-oxobutyric acid, cyclamate is determined as cyclohexene resulting from the reaction with nitrite, saccharin is converted to *N*-methylsaccharin, and stevioside is hydrolyzed. Detection is carried out utilizing flame-ionization, flame-photometric electron-capture detectors or nitrogen-phosphorus detection.

**Thin-layer chromatography and paper chromatography** Qualitative, semiquantitative, and quantitative

methodologies have been described for alitame, aspartame, cyclamate, glycyrrhizin, neohesperidine dihydrochalcone, saccharin, stevioside, and sucralose. Quantification is achieved using scanning densitometry.

**Capillary electrophoresis** Capillary electrophoresis techniques, such as capillary zone electrophoresis and micellar electrokinetic capillary chromatography have been used to analyze high-intensity sweeteners in foods. These methods are rapidly gaining acceptance for the determination of sweeteners because they are comparable in resolution and precision to LC, but are faster and less expensive to operate. Aspartame, saccharin, acesulfame-K, alitame, and the other food additives are well separated in less than 12 min using an uncoated fused-silica capillary column with a buffer consisting of sodium deoxycholate, potassium dihydrogenorthophosphate, and sodium borate operating at 20 kV. In the micellar electrokinetic chromatographic mode, carbonate buffer at pH 9.5 is used as the aqueous phase and sodium dodecyl sulfate is used as the micellar phase. The determination can be performed by direct or indirect (cyclamate) UV detection, or by potentiometric detection with coated-wire ion-selective electrodes.

**Electroanalytical techniques** Polarographic procedures are described for acesulfame-K, cyclamate, and saccharin. Cyclamate was decomposed by heating with sodium nitrite and the sulfate liberated is

precipitated as lead sulfate, and the excess of  $\text{Pb}^{2+}$  is the specie measured. Sensors including biosensors such as enzyme electrodes or filter-supported bilayer lipid membranes are proposed for acesulfame-K, aspartame, cyclamate, saccharin, and sucralose. A fluoride-selective electrode is used for the kinetic potentiometric monitoring of the reaction between 2,4-dinitrofluorobenzene and aspartame. Ion-selective electrodes based on ion associates, liquid membrane electrodes based on crystal violet and brilliant green, and silver electrodes are used for the potentiometric titration of saccharin.

**Spectrophotometric techniques** Extractive spectrophotometric techniques using colorimetric reagents (oxazine dye, Sevron blue 5G for acesulfame-K; *p*-dimethylaminobenzaldehyde, 1,4-benzoquinone, ninhydrin for aspartame; picryl chloride, *p*-quinone for cyclamate; vanillin for glycyrrhizin; Nile Blue, Azure A, B, or C, Sevron blue 5G, Brilliant cresyl blue for saccharin; and anthrone for steviosides) are used for the direct determination of the high-intensity sweeteners. Indirect spectrophotometric methodologies are also proposed. UV absorbance detection is possible for aspartame, cyclamate, glycyrrhizin, and saccharin. Nevertheless, as cyclamates are not readily detected by spectroscopic techniques, a chemical derivatization is performed; generally to convert it to cyclohexylamine. Fluorimetric determinations are suggested for aspartame, where its reaction product with fluorecamine is detected, and for saccharin since this forms a fluorescent complex with sodium carbonate. Flame atomic absorption spectrometry can be used for the indirect determination of saccharin and cyclamate.

**Titrimetric methods** Titrimetric assays have been developed for acesulfame-K (titrated with sodium methoxide in benzene), aspartame, sodium cyclamate, and sodium saccharin (titrated with perchloric acid), and for saccharin (acid form) with potassium hydroxide as titrant. Precipitation, chelatometric, and redox titrations are proposed for the determination of cyclamate. The oldest methods for saccharin involve its determination by means of a Kjeldahl procedure.

**Gravimetric methods** Cyclamate, saccharin, glycyrrhizin, and stevioside can be determined by gravimetric procedures. Those for cyclamate and saccharin are included in the method book of the Association of Official Analytical Chemists (AOAC).

## Bulk Sweeteners

Bulk sweeteners, defined as those delivered, in solid or liquid form, for use in sweeteners per se or in foods in quantities greater than 22.5 kg, are disaccharides and monosaccharides of plant origin. Sucrose from sugarcane and sugar beet and starch-derived glucose and fructose from maize (corn), potato, wheat, and cassava are the major sweeteners sold in bulk to the food and beverage manufacturing industry, or packers of small containers for retail sale. Relative sweetness of bulk sweeteners and their caloric values are shown in Figure 3.

### Caloric Sweeteners

**Sucrose** Sucrose is composed of one molecule of glucose and one molecule of fructose,  $\alpha$ -D-glucopyranosyl-D-fructofuranoside. It is the traditional sweetener, table sugar. It is highly water soluble and is present in most fruits, some root vegetables, many trees, and grasses. It is more concentrated in sugarcane, *Saccharum officinarum*, and the sugar beet, *Beta vulgaris*, the latter in temperate zones. From either crop, juice is extracted, purified, and concentrated to syrup. Sucrose is crystallized from the syrup by serial crystallization; the residual viscous syrup is molasses. From both crops comes a range of white sugar products: solid granulated, powdered, cubes, liquid sucrose, and invert syrups (blends of sucrose, glucose, and fructose). Primarily from sugarcane come brown sugars, edible molasses, golden syrups, and dark cane syrups.

**Molasses** Molasses, the residual material from sugarcane and sugar beet processing, is traded in bulk, primarily for animal feed where it is mixed with fibrous residues, and serves to increase caloric value and palatability. It is not sold as a sweetener, although it is blended with other sweeteners to make special syrups.

**Honey and maple syrup** Honey, produced by honeybees (*Apis mellifera* and *Apis dorsata*) is a liquid product, ~80% solids, containing a mixture of simple carbohydrates: 25–45% fructose, 25–45% glucose, 2–12% maltose, and 0.5–3% sucrose, with traces of many other sugars depending on the bees' floral source.

Maple syrup and sugar, made from sap of the sugar maple tree (*Acer saccharum*) through concentration and crystallization, are, like honey, mixtures of simple sugars. Freshly made maple syrup, generally ~65% solids by weight, contains 50–63% sucrose and 0–8% combined glucose and fructose,

**Figure 3** Relative sweetness for bulk sweeteners and their caloric values. HSH, hydrogenated starch hydrolyzates.

but no maltose. As maple syrup is stored, the sucrose will invert to glucose and fructose.

### Starch-Derived Sweeteners

**Glucose** Glucose, commercial name dextrose, in the aldohexose form  $\alpha$ -D-glucose ( $C_6H_{12}O_6$ ), is the major product from starch hydrolyzed by acid and/or enzymes. The major starch source in the USA and Japan is corn (*Zea mays*) and in Europe, wheat and potato. There is some starch and starch hydrolyzate production from cassava in the tropics. Glucose is sold as anhydrous dextrose; more commonly as dextrose monohydrate, as glucose syrup or corn syrup.

**Fructose** Fructose, in the ketohexose form  $\beta$ -D-fructose ( $C_6H_{12}O_6$ ), is produced from glucose by an isomerase enzyme (glucose–fructose isomerase), which converts glucose to fructose, and subsequent enrichment of the fructose fraction (equilibrium conversion is  $\sim 50\%$ ), or isolation of fructose and crystallization. Products are high-fructose corn syrup, the most widely used monosaccharide sweetener, at 42, 55, and 90% fructose (with glucose, the other major component) and crystalline fructose.

### Low-Caloric Sweeteners

**Sugar alcohols, polyhydric alcohols, or hydrogenated sugars** Sugar alcohols or polyols differ from sugars in that the aldehyde or ketone function of the sugar molecule is reduced to an alcohol. They can also be categorized as sugar substitutes because they can replace sugar sweeteners. Most common as bulk sweeteners are sorbitol, mannitol, xylitol, and erythritol

(monosaccharides); isomalt, maltitol, and lactitol (disaccharides); and hydrogenated starch hydrolyzates (HSH, a mixture of sugar alcohols). Many sugar alcohols are found in nature, but it is not commercially feasible to isolate and concentrate them from their sources. Sorbitol, mannitol, maltitol, and the HSH are produced by enzymatic hydrolysis of a starch. Lactitol, xylitol, and isomalt are produced in a similar manner, except that they are not derived from starch. Erythritol has been commercially produced by a fermentation process. All retain sweetness through heating and their bulking properties are similar to those of sucrose. All polyols are absorbed slowly and incompletely from the intestine by passive diffusion. Therefore, these sweeteners provide low energy and offer potential health benefits (e.g., reduced glycemic response and reduced dental caries risk). All these sweeteners except mannitol do not represent a hazard to health and the Joint Expert Committee on Food Additives of the Agriculture Organization/World Health Organization (JECFA) deemed it not necessary to assign a numerical value for ADI, but instead assigned the most favorable term ‘not specified’. Furthermore, in the USA they are considered Generally Recognized as Safe. Nevertheless, an excess consumption of mannitol may have a laxative effect, and for this reason, JECFA has allocated a temporary ADI of 50 mg per kg.

**Tagatose** This is a new low-calorie sweetener. It is a bulk sweetener, as it is used where the bulk (mass) of sugar is important to the final product qualities. It is a monosaccharide sugar derived from lactose. Therefore, tagatose is a naturally occurring sugar derived from dairy whey.

### Analytical Methodology

Analysis of bulk sweeteners falls into two categories: (1) chromatographic methods, used in starch hydrolyzate production and for most sweetener-containing products, and (2) polarimetric and wet chemical methods used in sucrose production. There are some UV-visible spectrophotometric methods for sugar analysis; these are generally used in clinical or biological sugar analysis, and not for bulk sweeteners, and so will not be further considered here. FIA methodologies have been developed for a large number of methods for the determination of bulk sweeteners, above all for reducing sugars. The most recent methodologies involve automation of enzymatic determinations and biosensors. Sample preparation procedures are shown in Table 3.

**Polarimetric methods** These methods generally determine some overall feature of the bulk sweeteners such as total carbohydrates. Polarimetry, using a flow-through polarimeter at 589 nm, is the general method of sucrose analysis in bulk raw and white sugars. Traditional polarimeters are being replaced by polarimeters using light of longer wavelengths,  $\lambda = 880$  nm, which can be used for monitoring

a colored (though not a turbid) solution, and so decreases solid waste generated in the clarification step required by traditional polarization.

**Titrimetric and other methods** Titration with a copper(II) salt (Lane–Eynon titration) is the standard method for the determination of reducing sugars (glucose and fructose) in bulk raw and white sugars.

Moisture in solid sugars is determined generally by oven drying; in liquid products, by Karl Fischer titration. Inorganic content is determined by either conductivity in solution, or sulfated ash gravimetric procedures.

In syrups, the solids content (Brix, or refractometric dry solids (RDS)) is determined by refractive index measurement. Tables correlating refractive index with sucrose and invert content are published in the International Commission for Uniform Methods of Sugar Analysis and AOAC methods books.

**Gas chromatography** This was the first quantitative chromatographic system for sugars analysis, but it has been replaced by liquid chromatographic methods, which are simpler, less expensive, and require no derivatization, except in the fermentation industries, where the ease of analysis of alcohols and other fermentation products along with starting (glucose,

**Table 3** Sample preparation procedures for analysis of bulk sweeteners

<i>Technique</i>	<i>Sample preparation procedures</i>
Polarimetry (589 nm)	White sugar: do not require clarification Raw sugar, brown and yellow sugars: addition of lead subacetate, along with a diatomaceous earth filter aid, with filtration to obtain a clear solution of little color. Subacetate can be replaced by an aluminum salt or ultrafiltration, but for raw cane sugar these reagents do not provide satisfactory clarification
Polarimetry ( $\geq 880$ nm)	Addition of diatomaceous earth before filtration
Titrimetry	Samples other than molasses require no pretreatment
GC	Sucrose, glucose, fructose, syrups, and sugar alcohols can all be analyzed with pretreatment derivatization of the sugars as either aldonitrile or trimethylsilyl derivatives Simple sugars and sweetened beverages: generally require only filtration through at least a 0.5 $\mu$ m filter to remove suspended solids
LC	Fats and proteins present in food must be removed. Fats by extraction with an organic solvent (petroleum ether) and extraction of sugars with water or water/ethanol mixtures; proteins by precipitation with a solution of zinc acetate–potassium hexacyanoferrate(II)–water
Enzymatic methods	Extraction with cartridges of an appropriate adsorbent For methodologies supplied in kit form: filtration of the dissolved sample For biosensors containing immobilized enzymes: generally requires only filtration. Time may also be required for treatment with enzymes other than the detecting enzyme, e.g., mutarotase treatment before glucose oxidase addition

GC, gas chromatography; LC, liquid chromatography.

sucrose, molasses) and intermediate materials has helped in the continuation of the use of this technique.

**Liquid chromatography** Four LC systems are in general use for analysis of bulk sweeteners and sugar alcohols (all systems require a sample with sugars concentration from <1 to 10% and the detection of separated peaks is usually by differential refractometry):

1. Separation on a cation-exchange column, in the calcium or sodium form, with an aqueous mobile phase. Cation-exchange columns separate by a combination of liquid exchange and size exclusion; higher molecular weight sugars elute earlier than the smaller sugar molecules, but after ionic inorganic components, because the smaller molecules complex more strongly with cations on the column. Sugar alcohols may be separated on these columns, but only with pulsed amperometric detection and long separation times.
2. Separation on an amino-bonded silane column with an acetonitrile–water mobile phase. These were the first LC systems utilized for the separation of carbohydrates. The main drawback is the use of acetonitrile as solvent, but its expense and hazard can be decreased by recycling the mobile phase over a desugaring adsorbent. The column separates sugars because of their varying affinities in an aqueous/acetonitrile solvent for the bonded amino groups on the packing material. Monosaccharides (glucose, then fructose) elute first, followed by di- and trisaccharides. This system is operated at room temperature. Analysis for trisaccharides or sugar alcohols can add 40 min to the normal 10–15 min analysis time.
3. Separation on reversed-phase columns with an aqueous mobile phase. This rapid and inexpensive system is used where only separation of mono- and disaccharides is required without further separation within either group. The nonpolar column packing is silica particles coated with octadecyl (C-18) groups. Separation occurs in order of decreasing polarity and, therefore, for bulk sweeteners, in order of molecular weight.
4. Separation on anion-exchange columns with an alkaline aqueous mobile phase. This system for sugar analysis, originally called ion chromatography, is now, for carbohydrates, more selectively called high-performance anion-exchange-pulsed amperometric detection. It has gained use in the general analysis of bulk sweeteners because of its versatility and selectivity. It is the preferred system for analysis of low levels of bulk sweeteners.

The selectivity and retention time may vary by changing the pH and ionic strength of the mobile phase. The responses of the detector, a gold electrode, may be set at specific potentials to analyze for specific carbohydrates. Sugar alcohols can be analyzed along with sugars in a single analysis; isocratic elution is usually satisfactory for food and beverage products, but gradient elution is available for more complex mixtures.

**Enzymatic methods** Enzymatic methods are available for the analysis of bulk sweeteners in food and beverages; enzyme electrodes and detection kits are available for several sweeteners (e.g., sucrose, glucose, etc.). The usage of enzyme methods is determined by conditions under which the enzyme is viable, i.e., heat, substrate concentration, water availability, and interferences. This methodology is a popular alternative to chromatographic methods due to its speed, portability, and wide range of application.

**Capillary electrophoresis** Recently, this technique has revealed its highest capability in separation of bulk sweeteners. Since bulk sweeteners lack both a charge and a strong UV chromophore, several derivatization reactions have been proposed (e.g., interaction with oxoacid or metal ions). An alternative for bulk sweeteners is their separation in a fused-silica capillary using indirect fluorescence detection or indirect UV detection. Electrokinetic micellar chromatography has extended the applicability of electrophoretic techniques even to neutral molecules such as carbohydrates.

**Stable isotope ratio analysis** Adulteration of fruit juices or honey by addition of bulk sweeteners can be detected by stable isotope ratio mass spectrometric analyses, because the naturally occurring carbon isotope ratio of  $^{14}\text{C}$  to  $^{12}\text{C}$  in honey and fruit is different from that in corn or sugarcane although not from that in sugar beet. The oxygen isotope ratio may be used for beet sugar addition.

**Near-infrared spectrometry** This is an alternative for the process analysis of bulk sweeteners, e.g., raw sugar.

### Preliminary Note

To distinguish between natural and synthetic fiber materials, the easiest method is to conduct a burning test. If a fiber based on natural material, with the exception of asbestos, is slowly moved to a flame, it starts to burn. Most synthetic fibers melt and burn only if the fiber is held directly onto the flame. Some synthetic fibers, e.g., Aramid, do not burn and can be distinguished under an optical microscope.

### Natural

**M Halbeisen**, EMPA St Gallen, St Gallen, Switzerland

This article is a revision of the previous-edition article by Ira Block, pp. 5116–5122, © 1995, Elsevier Ltd.

### Introduction

Fibers based on natural materials are divided into two categories: natural fibers found in the plant, animal, and mineral kingdoms; and regenerated cellulosic fiber, which are manmade fibers made out of natural polymers.

Plant fibers are cellulosic, animal fibers are proteinaceous materials, and asbestos is a crystalline silica compound. Almost every fibrous material has had some use in historic or prehistoric times. The most important natural fibers used in the textile industry are: cotton, linen, wool, and silk (moth silk) (see **Table 1**).

Regenerated cellulosic fibers are made out of cellulose from wood or cotton lint. The most used fibers are viscose, acetate, cupro (very small quantity), and lyocell. These fibers are produced in various titers as filament (endless fiber) or staple fiber.

### Fibers

#### Cotton

This is the most abundant fiber, accounting for ~40% of the world's production of all fibrous materials. The fiber is the seed hair of plants of the genus *Gossypium* and exists in many commercial varieties, e.g., Egyptian, Sea Island, and Uplands. Its appearance is quite characteristic; it is a flattened, twisted hollow tube, as shown in **Figure 1**. Commercial fibers range in length from 0.3 to 5.5 cm, are ~10 µm in diameter, and generally have dull white color.

The structure of the fiber comprises a thin, dense outer shell (the primary wall) surrounding many

concentric cellulose layers (the secondary wall) that enclose a hollow core (the lumen). The primary wall is composed of cellulose containing small amounts of various vegetable oils and waxes. The secondary wall consists of numerous chains of cellulose deposited in layers within the tube formed by the primary wall. This deposition occurs as the glucose in solution polymerizes to cellobiose with a degree of polymerization (DP) of  $\sim 3000$ . That is, on average, each cellulose chain is made up of 3000 cellobiose units. The lumen is the hollow tube that is left when all the glucose solution from which the fiber was created has been used up or dried out. The fiber is made up of over 95% cellulose.

Morphologically cotton cellulose is highly crystalline. Estimations of the extent of crystallinity vary, depending upon the measurement method used, from  $\sim 75\%$  to  $95\%$ . This configuration is almost a rectangular parallelepiped containing a cellobiose unit in each corner, with a central cellobiose unit in the center, antiparallel to the other four.

Mercerized cotton has a different structure. With the use of a strong alkaline process, cotton fibers swell. The cross-section of mercerized cotton is round, like the premature cotton, and untwisted.

### Linen

Linen is the fiber taken from the stem of the flax plant, *Linum usitatissimum*. Photomicrographs of the cross-section and longitudinal view are shown in Figure 2. Commercial linen consists of bundles of individual fibers cemented together by lignin as well as vegetable waxes. The cement accounts for  $\sim 30\%$  of the weight of the fiber. The remainder is cellulose. Individual fibers range in length from  $\sim 4$  cm to 1 m and are  $\sim 20 \mu\text{m}$  in diameter. The color of linen is whitish blonde.

Individual fibers have a bamboo-like structure consisting of single cells, length ranging from  $\sim 0.3$  cm

**Figure 2** Cross-section (A) and longitudinal view (B) of typical linen fibers. (Originally published in the AATCC Technical manual, as a part of AATCC Test Method 20; reprinted with permission from the American Association of Textile Chemists and Colorists.)

to as much as 5 cm, joined end to end. These cells are composed of smaller fibrils surrounding a thin lumen and give the longitudinal view of the striated appearance seen in **Figure 2**. The junctions of the cells produce a slight swelling, called nodes, that are characteristic of bast fibers. Lignin, a component of all woody plants including flax, is a complex, cross-linked, tarry substance, whose structure has not yet been clearly defined.

Morphologically, the cellulose in linen is in the Cellulose I form, with a DP of  $\sim 3000$ . The chains within the cells form an extended helix that is nearly straight and almost parallel to the fiber axis. They do not exhibit the reversals of direction found in cotton.

## Wool

Chemically and structurally, wool is typical of all animal hair and fur. Its major constituent is the

**Figure 3** Cross-section (A) and longitudinal view (B) of typical wool fibers. (Originally published in the AATCC Technical manual, as a part of AATCC Test Method 20; reprinted with permission from the American Association of Textile Chemists and Colorists.)

protein 'keratin'. Wool fibers range in length from 2 to 50 cm and from 10 to 20  $\mu\text{m}$  in diameter. The fibers of the highland sheep (e.g., merino) are highly crimped and shorter, compared to the lowland sheep (e.g., cheviot), which are low or uncrimped and longer. They may be white, brown, gray, or black. The finest wools are taken from young lambs. In its natural state, wool contains a high percentage of lanolin, a water-repellent oily material that is often removed in processing.

The cross-section and longitudinal views of wool are shown in **Figure 3**. **Figure 4** is a schematic diagram of the structure of the fiber. Enclosed within an outer scaly layer of keratin (the cuticle) are three sets of cortical cells: *para*, *meso*, and *ortho*. The cells may surround a hollow core, known as the medulla.

The *para* cells are characterized by close-packed microfibrils and a high cystine content. The *ortho*

**Figure 4** Cutaway view of the wool fiber.

cells have their microfibrils more widely spaced, a lower cystine content, and a high concentration of glycine and tyrosine. The *meso* cells have properties in between those of the *ortho* and *para* cells. Highly crimped wools are those with a preponderance of *para* cells while those with little crimp contain mainly *meso* and *ortho* cells.

### Silk

Silk, obtained from the cocoon of the silk moth *Bombyx mori*, is the only natural filament fiber. It is composed of the protein 'fibroin'. Unlike wool, silk has an extended chain, pleated-sheet morphology, the  $\beta$ -helix. The  $\beta$ -form permits a much greater degree of intermolecular hydrogen bonding than does the  $\alpha$ -form, so that the crystallinity of silk is much higher than that of wool. Thus, silk is somewhat stronger than wool, even though it lacks cystine to provide cross-links. The cross-section and longitudinal views of silk are shown in Figure 5.

### Viscose

Viscose fibers – also known under the name rayon – are manmade cellulosic fibers. Cellulose – extracted from wood (wood pulp) – reacts with 18% caustic soda to give alkali cellulose, which is treated with carbon disulfide after the so-called preripening (breakdown of the cellulose molecules into smaller units), the white alkali cellulose changing into orange-yellow cellulose xanthogenate. Diluted

**Figure 5** Cross-section (A) and longitudinal view (B) of typical silk fibers. (Originally published in the AATCC Technical manual, as a part of AATCC Test Method 20; reprinted with permission from the American Association of Textile Chemists and Colorists.)

caustic soda dissolves the xanthogenate into a syrup mass, the spinning solution or viscose, after which this method of operation has been named. Pumped through the holes of the shower-like spinnerets (5000–250 000 holes) into a flowing spinning bath, which contains diluted sulfuric acid, sodium sulfate, and zinc sulfate, the viscose coagulates into fine white filaments of pure cellulose.

Viscose fibers have nearly the same physiological properties but poorer physical properties than cotton.

### Acetate

For the production of acetate and triacetate, high-grade cellulose – e.g., cotton lint – is converted into cellulose acetate with acetic anhydride, and dissolved in acetone. In contrast to triacetate, only 2.5 of the three hydroxyl groups of a basic cellulose unit are

esterified ( $2\frac{1}{2}$  acetate or diacetate). The viscous spinning solution is pressed through spinnerets, falling through 3–6 m high spinning ducts where the volatile solvent acetone is evaporated. The dissolved cellulose acetate is transformed into solid, filament yarns with a silk-like luster.

Acetate is thermoplastic and the softening rate has a range between 205°C and 215°C. The fibers are soluble in acetone.

### Lyocell

The production of lyocell is a new technology for producing cellulosic fibers by means of a direct solvent process. This means that a genuine solution of the cellulose in *N*-methylmorpholine-*N*-oxide (NMMO) monohydrate is produced and spun, and not a cellulose derivate as in the case of viscose. The cellulose can, however, be obtained from used textiles or by crushed wood pulp. After filtration of the honey-like spinning solution, it is spun through an air gap into diluted aqueous NMMO solution.

Lyocell has nearly the same physiological properties as cotton and the physical properties are much better than viscose.

## Fiber Identification Methods

### Ignition

Burning tests are the simplest means of determining the generic class to which an unknown fiber may belong. Protein fibers – all fibers from animals – burn slowly, with a smoky, sputtering flame and give off a characteristic odor of burning hair. Natural and regenerated cellulose fibers – with the exception of acetate – are readily ignited and burn rapidly. A glowing red cinder is obtained after burning, along with the characteristic odor of burning paper.

Acetate is not a pure cellulosic fiber, and so the ignition is completely different. They burn very quickly, first as a melted ball and later as gray ash. The odor is acidic. Mineral fibers do not ignite or burn.

### Microscopy

Having determined that a fiber is either of animal or vegetable origin, examination under a 10–20× microscope is often sufficient to identify it. If, for example, one has an animal fiber, comparison of the specimen with a known, previously mounted standard allows one to readily differentiate the various fur and hair fibers. Wool is easily distinguished from camel hair or rabbit fur by the types of scales and size of medulla. Further comparison with samples taken from different breeds of sheep will yield a more exact

identification. The use of a scanning electron microscope is also possible, especially if there are very fine details to show. Similarly, seed hair, leaf, and bast fibers also possess distinguishing characteristics. It should be recognized that this method will not permit one to identify the exact animal or plant from which a fiber may have been taken. More sophisticated instrumental methods are usually required and some are discussed below.

### Solvents

Various fibers may be identified, or separated from each other, through sequential dissolution in various solvents. As seen in Figure 6, silk is soluble in HCOOH/ZnCl<sub>2</sub>, while wool does not dissolve. For bast fibers it is possible to discern some types with phloroglucin/HCl under a microscope. Jute will stain red, while hemp is only slight pink, and ramie and flax are unaltered. With the use of Kuoxam, ramie is dissolved while flax remains undissolved. For these tests, it is absolutely necessary to use reference materials!

This technique is not capable, however, of distinguishing between different wools or between different silks.

### Stains

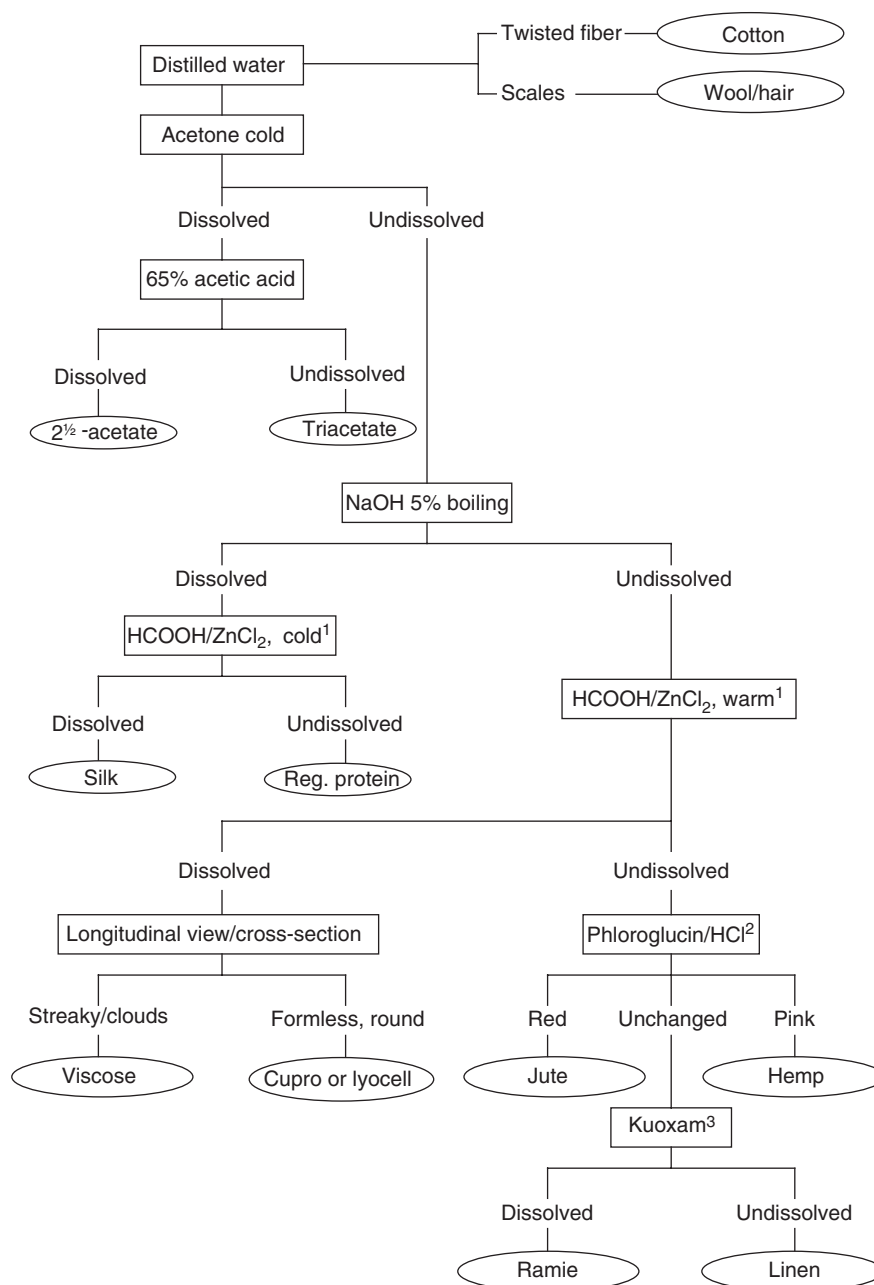

Fibers may be identified by their response to different dyes. Animal fibers readily take up acid dyes, while plant fibers are more responsive to direct dyes. Combinations of dyes that will permit identification of different fiber types are commercially available. The most common commercial solution is Neocarmin. See technical literature or the Internet for more information. As in solvent testing, however, this technique is not suitable for making distinctions among similar fibers.

### Instrumental Methods

Infrared (IR) spectroscopy and Fourier transform infrared (FTIR) spectroscopy can be used to distinguish between generic classes of fibers, i.e., cellulose fibers and proteins, as each have characteristic absorption bands. A variation of this technique, FTIR-photoacoustic spectroscopy can nowadays be used to determine the extent of cross-linking in cotton fabrics treated with polycarboxylic acids by measuring the absorption at 1725 cm<sup>-1</sup> of the ester groups formed.

Polyacrylamide-gel electrophoresis in sodium dodecyl sulfate combined with staining by Coomassie Blue could be used to distinguish among merino wool, mohair, and cashmere.

Analysis of DNA by polymerase chain reaction has also been shown to be a useful, but expensive, means of distinguishing between different hair and wool fibers.

<sup>1</sup>20 g water-free  $\text{ZnCl}_2$ , dissolve in 80 g formic acid 85%.

<sup>2</sup>10% Phloroglucin (alcoholic solution) mixed with the same quantity HCl 100%.

<sup>3</sup>8 g  $\text{CuSO}_4 \times 5\text{H}_2\text{O}$  dissolved in 40 ml distilled water. Add 10 g  $\text{NH}_4$  and fill up with distilled water to 100 ml. Then add 4 ml NaOH 20%. If cotton dissolves quickly, a lower quantity of NaOH should be used.

**Figure 6** Reaction diagram for solvent tests.

## Fiber Characterization

The properties and performance of the natural fibers are dependent upon both their macrostructure (large-scale physical features) and their microstructure (chemical composition). The major macrostructural

characteristics of importance in the use of these fibers are the length, crimp, and fineness.

### Macrostructure

Fiber length is measured by combing the fibers of a given sample, sorting these fibers according to length,

measuring the length of the individual fibers, and determining a histogram of the length distribution. Over the years, the procedure has been instrumented and image analysis is often used.

Fiber crimp (waviness) affects the ease with which fibers may be spun into yarn, as well as many of the comfort characteristics of cloth made from those yarns. Computerized image analysis techniques can be used to measure the degree of crimp of a fiber.

Fiber fineness is determined by compressing a standard weight of fiber into a known volume and measuring the rate of airflow through the compressed mass under standard conditions. The result is known as the Micronaire reading. Various instruments have been developed to measure the fineness of wool and cotton fibers.

### Microstructure

The size and arrangement of macromolecules within a fiber and the chemical structure of those molecules determine many of the physical and, of course, all its chemical properties. Molecular weight, crystallinity, substituent groups, and chemical moieties introduced as a result of processing or use are the major microstructural factors.

The physical and mechanical properties of fibers are a consequence of their macromolecules of very high molecular weight. Thus, both from commercial and scientific viewpoints, molecular weight measurements give important insights into the structure and behavior of these materials.

The molecular weight of the natural fibers is determined by standard procedures. End-group analysis is less useful for natural fibers, which do not yield unambiguous results, than for the synthetic polymers. Physical methods, such as viscometry, osmotic pressure, and light scattering, are all appropriate for the natural fibers. Gel chromatography is not generally used because it is more intricate than the other methods without yielding more significant information. The reader is referred to standard texts on polymer science for these procedures.

### Crystallinity

The natural fibers exhibit varying degrees of crystallinity. Although simple models that assume a given fraction of perfectly crystalline material existing within a matrix of perfectly amorphous material are suitable for estimating fiber mechanical properties, fiber morphology spans the full range from perfect crystal to perfect glass. The degree of crystallinity affects both mechanical and chemical properties, in that it is the crystalline regions that give a

fiber its strength, while the extent to which reactive moieties are accessible to chemical reaction is determined by the amount of amorphous material.

Crystallinity may be measured by chemical reaction, such as hydrolysis, deuteration, or saponification, or by physical methods, which include X-ray diffraction, density, IR spectroscopy, and birefringence. It should be noted that, since each of these methods measures a property that is affected by crystallinity in different ways, agreement among the different methods is rare.

### Chemical Reactivity

The chemistry of the cellulosic fibers is similar to that of the simple sugars, but more complex, as the stereochemistry of the alcohol and hemiacetal structures is affected by degree of crystallinity, e.g., the  $-OH$  groups on the carbon atoms 2, 3, and 6 have different reactivities. Reaction with mineral acids leads to cleavage of the glycosidic bond and formation of a reducing end ( $RO-CH-OH$ ).

The number of these ends, and thus the extent of degradation, is determined by reacting a fiber sample with Fehling's solution to produce copper(I) oxide. The result is known as the 'copper number'. Cellulosic fibers degraded in this manner are known as hydrocelluloses.

The major environmental effects on cellulose are oxidation of the hydroxyl groups and hydrolysis of the glycosidic bonds. Both atmospheric acidity and light are the major catalysts for weathering. Oxidation of cellulose leads to the formation of carbonyl ( $C=O$ ), carboxyl ( $COOH$ ), and shorter-lived peroxy ( $COO$ ) species. Carbonyl groups may be measured by titration with silver nitrate. Carboxyl species are determined by reaction with methylene blue dye. Peroxides, formed in greater quantity by light than by heat, are determined by measurement of the absorbance of a phenolphthalein-copper(II) sulfate solution that has reacted with a weighed amount of oxidized fiber.

Both carbonyl and carboxyl species are revealed, semiquantitatively, by the growth of a peak in the IR spectrum at  $\sim 1740\text{ cm}^{-1}$ . In addition, carbonyl groups produce an increase in absorption in the ultraviolet region at  $\sim 265\text{ nm}$  and are thought to be the chromophore that leads to the yellowing of celluloses.

In the absence of oxygen, cellulose is highly resistant to alkali. Oxidized cellulose, however, is far less resistant to alkaline hydrolysis as formation of  $C=O$  groups adjacent to the glycosidic bond greatly weakens it. Celluloses that have been oxidized, either with oxygen or more specific oxidizers such as periodate, are known as oxycelluloses leading to the destruction of the material.

The chemistry of the protein fibers is more complex. Amino acids exhibit amphoteric behavior in that they contain both a Lewis base (the amine) and a Lewis acid (the COOH). In acid media the active hydrogen exists in the form of an ammonium ion ( $-\text{NH}_3^+$ ), while in basic media the negative ion is the carboxylate ( $-\text{COO}^-$ ). In addition to the peptides of the backbone chain, the pendant groups in protein fibers provide additional reactive sites.

Acids cause hydrolysis of the main-chain peptides, while alkalis are less selective in their action. They may react with the carboxylic acids found in the aspartic acid, glutamic acid, and proline components, with the amino groups in arginine and lysine residues, or with the S–S bond in cystine, as well as with the main-chain links.

Cystine is important in the chemistry of the wool fiber, since the disulfide ( $-\text{S}-\text{S}-$ ) links form the intermolecular cross-links that give the fiber its coherence. Cystine is stable to acid, but readily attacked by dilute alkali. Mild oxidants such as hydrogen peroxide, the preferred bleach for protein fibers, will slowly convert cystine to cystic acid. Oxygen, in the presence of light also reacts with cystine, but its major effect is to attack the tryptophan residues and produce yellowing of the fibers.

## Introduction

Fibers, the basis for most textiles, consist of natural fibers, chemically modified natural fibers, or synthetic fibers (a description of the differences of these fiber types is given in the article).

Synthetic fibers, the subject of this article, are produced from linear synthetic polymers by different spinning processes. Depending on whether the process is based on polymer melt or polymer solution, the processes are divided into dry or wet spinning.

According to DIN 60001-T4, the synthetic fibers are divided into materials synthesized by different chain building processes: polymerization, polycondensation, and polyaddition. Polymerization is subjected to monomers containing a vinyl group (double bond) in the molecular structure. The chain reaction will be induced by radical reaction. Polycondensation

reaction needs bifunctional monomers, which are connected to a polymer chain by condensation reaction (secession of water or other small molecules). Polyaddition also needs bifunctional monomers but the formation of molecular bonding releases no side-products. The most common fiber forming polymers produced with polymerization reaction are: polyethylene, polypropylene, poly(vinyl chloride), poly(vinylidene chloride), poly(vinyl alcohol), polyacrylonitrile, polytetrafluoroethylene. Polycondensation and polyaddition leads to polyester, polyamide (PA), aramid, and polyurethane. **Figure 1** summarizes the principles of the chain forming reactions, chemical details of the concerned monomers regarding functional groups, and the resulting polymers. Besides the above-mentioned homopolymers (homopolymer = polymer derived from only one monomer type or a monomer couple), there exists a huge variety of the so-called co-polymers, which are polymers derived from two or more monomers. Additionally, two different polymer types may be extruded simultaneously in the same spinning

The chemistry of the protein fibers is more complex. Amino acids exhibit amphoteric behavior in that they contain both a Lewis base (the amine) and a Lewis acid (the COOH). In acid media the active hydrogen exists in the form of an ammonium ion ( $-\text{NH}_3^+$ ), while in basic media the negative ion is the carboxylate ( $-\text{COO}^-$ ). In addition to the peptides of the backbone chain, the pendant groups in protein fibers provide additional reactive sites.

Acids cause hydrolysis of the main-chain peptides, while alkalis are less selective in their action. process to produce bi-component fibers or blend fibers. Thus, an almost unmanageable number of different fibers with different properties exist.

The entire range of properties of a synthetic fiber depends especially on the molecular composition (monomers and tacticity; 'tacticity' means the geometric regularity of polymer side chains) and the

chain length of the polymer. Also, a marked influence on the mechanical properties is raised by the manufacturing conditions. Strength and tensile behavior (e-modulus), crystallinity and density, thermal properties (melting and glass transition points), moisture absorption, and solubility are some properties that can be mentioned in this connection. **Tables 1 and 2**

summarize the basic properties of a few typical synthetic fibers made from basic polymers. In the following, the analytical methods to investigate the physical, mechanical, and chemical properties of synthetic fibers will be discussed. Methods to analyze the molecular weight are also introduced. Most methods are not specific to fiber materials but generally are suitable for analysis of polymeric materials.

## Analysis of Mechanical and Physical Properties

### Strength and Elasticity

Strength and elasticity properties play an important role in both the production and the utility of textiles. Apart from finished products, fibers and yarns are also investigated to determine their strength. In most cases, this is done by means of a tensile test on prior conditioned fibers (standardized conditions: 20°C/65% RH). The material tensioned between two clamps is increasingly loaded along its axis until it breaks. If the load and the elongation (change in length) are plotted during this process, the resultant graph shows a load–elongation or stress–strain diagram (see Figure 2).

**Figure 2** Load-elongation (stress–strain) diagram with typical curves of a tensile test: (A) with, and (B) without a maximum point (maximum tensile strength).

The maximum force plotted in the load–elongation diagram is described as the maximum tensile strength (also tearing strength). The associated elongation is the elongation at maximum tensile strength (tear elongation). Textiles can often be further elongated to ultimate rupture. This is termed the elongation at break, and the associated force is termed the breaking load.

In comparing the strengths of textile fibers and yarns, however, it is more convenient to use a measurement based on the linear density of the fiber: tenacity (or specific load), expressed as N/tex. The tensile elongation undergone by the fiber is defined as the percentage change in sample length, or percentage extension.

The initial slope of the load–elongation curve is a measure of the extent to which the fiber resists stretching for small extensions. This property is termed the ‘modulus of elasticity’ (E-module). The E-module of fibers is a fineness-related force. It is quoted in cN/tex.

Fibers that show a steep initial slope (high E-module) usually break soon after the yield point. If, however, the stress–strain curve flattens out and continues on, the fiber will yield under high loads. If the applied stress is removed before the breaking point, the fiber may partially recover from extension. This ‘elastic recovery’ is defined as elastic extension (or distance recovered) divided by the total extension (usually expressed as a percentage).

The mechanical properties of textile fibers, yarns, and fabrics may be more fully determined by subjecting the substrate to small forces in directions other than along the fiber axis. Tear, bending, and shear strengths, as well as recovery from bending and abrasion resistance, etc., also influence the wear properties of textiles. Finally, time-dependent extension and recovery, termed creep, or creep recovery, respectively, is of importance in determining the performance of fibers in industrial applications. A discussion on the measurement of these parameters, however, is beyond the scope of this article.

### Crystallinity and Density

Synthetic polymers usually consist of a crystalline part and an amorphous part (ordered and disordered regions on the molecular scale). Besides the molecular composition, the degree of the crystalline fraction largely determines all physical characteristics of textile fibers. Fibers with a high degree of crystallinity exhibit high densities and high tensile strengths. Crystallinity is induced by three main factors: high chain linearity, regular tacticity of the side chains, and/or strong interchain attractive forces. These forces can be exemplified in polyester and nylon. Whereas the cyclic units in polyester enforce a rigidly linear chain conformation, the polar amide linkages in nylon allow the establishment of strong hydrogen bonding forces between polymer chains. Thus, both polymers are able to form highly crystalline conformations.

The most common method to analyze the crystallinity in fibers is X-ray analysis. The degree of sharpness versus diffuse scattering of an X-ray pattern produced from a synthetic fiber is a reliable indication of the relative proportion of its crystalline and amorphous fraction. Additionally, the spacing between rows of ‘reflections’ provides information on the distance of polymer repeating units. Based on theoretical calculations, further information on the extent of chain folding, and the stereochemical structure (tacticity) of a vinyl polymer, can be indicated. An approximation of crystallite size may also be obtained from the degree of diffuseness of the discrete spots on the X-ray diagram. In all polymeric systems the molecular chain length is much greater than crystallite length; hence, a single polymer chain is considered to interconnect through a network of several crystalline and amorphous regions.

### Thermal Properties

As already mentioned above, polymeric materials always consist of a crystalline phase and more or less an amorphous phase (glassy like). Thus, when polymers are heated they usually show two different thermal transition incidence connected to these two phases. The first, the so-called glass transition ( $T_g$ ), is connected with the amorphous state. It means the reversible change of a (partially) amorphous material from a hard and relatively brittle to a viscous or rubbery one. From the thermodynamic point of view  $T_g$  is a so-called second-order transition not connected with a change of the state of aggregation, but a change in molecular mobility. The second thermal transition is the melting point ( $T_m$ ). The melting point is known as a first-order transition. This transition occurs over a relatively narrow range, and is associated with the melting of crystallites within the polymeric system. Generally,  $T_g$  increases with increase in  $T_m$  (as a rule of thumb:  $T_g$  is around two-thirds of  $T_m$  (K)). In addition to these phase transitions ( $T_g$  and  $T_m$ ), chemical reactions and eventual irreversible decomposition may also occur whilst heating.

The most extensively used methods for monitoring these heat induced changes in fibers are differential thermal analysis (DTA) and differential scanning calorimetry (DSC). In DTA, both sample and inert reference are heated at the same rate by the same heat source. When a thermally induced transition occurs in the sample, a temperature difference between the sample and reference results can be recognized. A plot of the difference in temperature between the two against increasing applied temperature exhibits deviations from the initial baseline, depending on

whether the transitions are endothermic or exothermic. These are characterized by a downward or upward deflection, respectively, in the thermogram. The temperature range of interest is usually 25–400°C (at 400°C most polymers decompose). DSC is similar in concept to DTA, but in the case of DSC the heat flow from the oven to the sample is recorded. Integrating the heat flow over time the enthalpy change of a sample can be directly measured with DSC. Thermal transitions are highly characteristic and reproducible, and hence may be used for fiber identification. Especially for moisture absorbing synthetic fibers it has to be pointed out that the glass transition decreases significantly with increasing moisture content. The  $T_g$  of PA 6 in dry condition is ~65°C, but for 'wet' PA 6 the  $T_g$  is close to room temperature!

Dilatometry and thermomechanical analysis (TMA) are also techniques used to monitor the thermal behavior of fibers. They both employ a sensitive probe in contact with the surface of the sample, and the thermal transitions are detected either by a change in volume or modulus of the sample, respectively. In the latter case, the probe necessarily penetrates the sample surface. A variable transformer records the voltage output that is directly proportional to the degree of displacement of the probe during a thermally induced transition. TMA is a more sensitive technique than either DTA or DSC for detecting thermal transitions.

### Moisture Absorbance

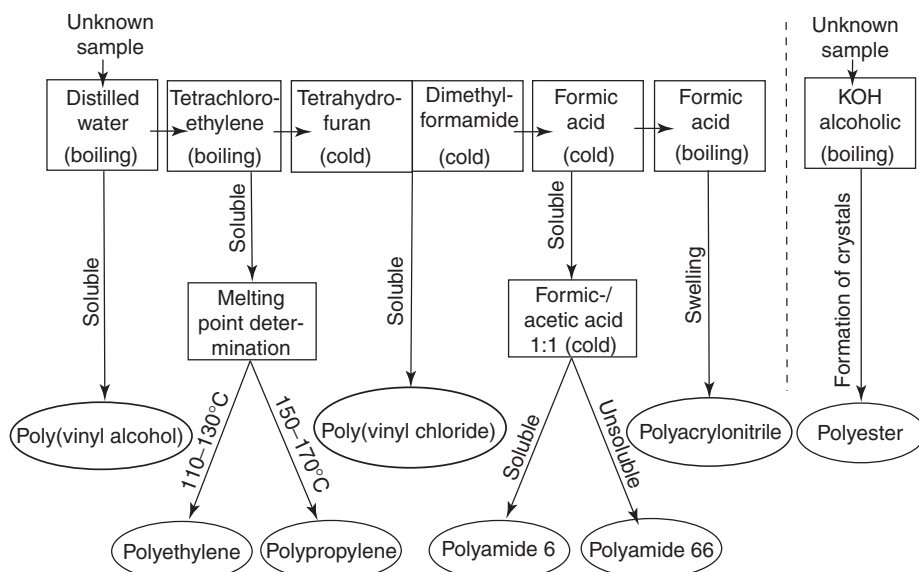

The tendency of a fiber to absorb moisture (water and/or water vapor) depends on the chemical

constitution of the fiber and is defined as the percentage of weight of moisture present in a fiber. The measurement of the moisture content can either be simply realized by the determination of the oven-dry weight (in case of high amounts) or due to more sophisticated methods for lower quantities of moisture. These methods are based upon vaporization of the moisture. The water content is then measured either by means of a coulometric Karl–Fischer titration or due to the measurement of the partial pressure of hydrogen. The hydrogen is released from a gas-phase reaction from water with calcium hydride (a corresponding machine named 'Aquatrac' has been commercialized by Brabender OHG, Duisburg, Germany).

A clear trend is recognized between fiber polarity and moisture uptake. The amount of polar amide (NH–CO) linkages and hydroxyl (OH) pendant groups into the methylene chain structures of polyamide and poly(vinyl alcohol) fibers, respectively, render them significantly more moisture absorbent (4–5%) than the polyolefins and elastomeric fibers (less than 0.1%). Densely packed polymer networks, as in the cases of polyester, poly(vinyl chloride), and particularly Kevlar fibers, exclude the entry of water molecules, again resulting in low moisture content.

### Solubility

The solubility of synthetic fibers in different inorganic or organic solvents depends, as most other properties, on the crystallinity and the chemical constitution of fibers. These differences in solubility can be used to distinguish between synthetic fibers in a simple way. The scheme in Figure 3 shows the way

**Figure 3** Schematic procedure for the determination of an unknown fiber sample due to differences in solubility.

for the characterization of an unknown synthetic fiber through application of different organic/inorganic media. A more effective and also easy characterization of unknown synthetic polymers can be realized with infrared (IR) spectrometry (see later).

### Microscopic Analysis

The characteristic features of a fiber are readily visible by light microscopy, within magnification levels of 200–400 $\times$ . The longitudinal sections of synthetic fibers, however, are rather smooth and structureless, and cross-sections of any desired shape may be produced; hence, microscopic examination of a fiber's appearance is not a useful tool for identification purposes. The cross-sections of synthetic fibers are mostly round or trilobal. Other existing forms are dog-bone or bean-shaped and many others (see Figure 4).

The dispersion of TiO<sub>2</sub> or the regularity of pigments is well visible under an optical microscope. With the use of polarization microscopy it is possible to control the linearity of the quenching process. Nonlinear quenched fibers are recognized by a color change.

In certain instances it may be of interest to examine the etched surface of a fiber or determine the proportion of a particular cross-section in a fiber mixture. This is done by scanning electron microscopy (SEM), where magnifications of up to 100 000 $\times$  can be achieved with greater depth of focus and resolution. Additionally, the cross-sectional appearance of bicomponent and polyblend fibers may be examined by SEM, revealing 'side-by-side' (Figure 4), 'sheath-core', or 'island-in-the-sea' composites.

## Analysis of Chemical Constitution

### Infrared Spectroscopy

This method of analysis is suitable for fiber identification, as well as for characterization of any chemical differences between two fibers of the same class. For instance, acrylic and modacrylic fibers containing copolymers of varying constitution and proportion may be identified. Identification depends on matching the additional bands with those in the IR spectrum of a fiber whose identity is already known. Both the wavelength and intensity differences of bands in each spectrum must be taken into account. Fiber samples may be prepared in the form of a pressed disk, where very finely divided particles of the fiber are uniformly distributed in powdered potassium bromide. The mixture is pressed into a small disk of about 1 mm thickness in a vacuum die under

pressure. Alternatively, a solvent-cast film of the fiber may be prepared. A suitable solvent for dissolving the fiber is necessary. A solution of the fiber is placed on a glass surface, and the solvent is carefully evaporated, preferably in a vacuum, so as to avoid bubble formation. The sample film is peeled from the glass plate and analyzed directly.

An extremely convenient instrumental technique that may be used to measure the IR spectrum of fibers or fabrics without prior preparation is attenuated total reflectance (ATR) spectroscopy. The technique is based on obtaining an IR absorption spectrum of a sample that is in contact with a reflecting surface. The incident IR beam is directed into the reflecting plate at an angle greater than the 'critical angle'; the beam is subsequently reflected after penetrating a few micrometers into the sample. A very simple to use ATR equipment suitable for almost all IR spectrometer types is the so-called 'Golden-Gate' accessory (commercialized by Grasby Specac Ltd., St. Mary Cray, Orpington, UK). All sorts of samples, liquids, powders, granules, fibers, etc., can be measured directly without any prepreparation of samples.

### NMR Analysis

Nuclear magnetic resonance (NMR) spectroscopy is a powerful but theoretically complex analytical tool. It can be used for the wide field of the structure analysis of organic materials. Also, synthetic polymers can be analyzed with NMR spectroscopy as long as the materials are soluble in suitable solvents (almost always chloroform). A specific application for NMR analysis in the field of synthetic fibers is the analysis of spin finish (processing aid). For this special application the fiber material is analyzed regarding the amount of protons in the solid and the liquid phase. The 'liquid protons' can be assigned to the amount of spin finish, if the technique is pre-calibrated well. Analysis time is typically 1 min per sample and no sample preparation is required. Thus, NMR is a rapid and accurate alternative to the solvent extraction techniques and can be used as an almost online production control (a corresponding machine for spin finish analysis by NMR is commercialized by Oxford Instruments Ltd, Abingdon, Oxon, UK).

## Analysis of the Molecular Weight Distribution

Due to the mechanism of polymerization processes (radical polymerization as well as polycondensation), all polymers exhibit a more or less pronounced distribution of polymer chain length, which means that

**Figure 4** (A) Acrylic fiber (Orlon 42). Dogbone-like cross-section shape;  $\times 750$ . (B) Acrylic fiber (Acrilan). Bean-shaped cross-section;  $\times 240$ . (C) Modacrylic fiber (Dynel). Deeply-fluted structure;  $\times 750$ . (D) Modacrylic fiber (Dynel). Folded shapes with deep re-entrants;  $\times 750$ . (E) Nylon 6,6, trilobal cross-section;  $\times 300$ . (F) Bicomponent polyester fiber, side-by-side type cross-section;  $\times 160$ . (Reproduced with permission from Lewin M and Pearce EM (eds.) (1985) *Identification of Textile Materials*, 7th edn. Manchester: The Textile Institute.)

no polymer consists of uniform molecules, where all chains have the same length with the same number of repeating units (monodisperse distribution). Thus, from polymers only average molecular weights, molecular weight distributions can be determined. But the knowledge of that is an important analysis

for every polymeric system. Especially for polymers subjected to a spin process the knowledge of these data is essential. If the molecular weight is too high, the melt viscosity may be too high for spinning process; if it is too low, adequate tensile properties may not be achieved.

The average molecular weight may be determined as a number average or weight average depending on the method of measurement. In the former case, the molecular weight is based on the mole fraction (or sample weight per mole), while in the latter case, the weight fraction determines the average molecular weight:

$$M_n = \frac{\sum M_i N_i}{\sum N_i} \quad M_w = \frac{\sum N_i M_i^2}{\sum N_i M_i}$$

where  $M_n$  is the number average molecular weight,  $M_w$  the weight average molecular weight,  $M_i$  the molecular weight of each species, and  $N_i$  the number of moles of each species.

$M_w$  is therefore greater than  $M_n$ , and the ratio  $M_w/M_n$  is indicative of the molecular weight distribution of a polymer sample (polydispersity  $P$ ). The more similar these values, the narrower the molecular weight range.

The most widely used method for determining molecular weight distribution for fiber forming polymers is gel permeation (size exclusion) chromatography (GPC or SEC). Other commonly used methods in this case are end group analysis, osmometry, and viscometry. These methods are also introduced below.

### Gel Permeation Chromatography

GPC (or SEC) is generally the technique of choice in determining the molecular weight distribution of synthetic fibers that are soluble in common organic solvents like tetrahydrofuran or chloroform. The technique is based on chromatographic separation of polymer molecules according to size by elution through a column of porous material (cross-linked polystyrene or silica gel). The smaller polymer molecules diffuse into the pores of the packing material and thus elute more slowly; the higher molecular weight fractions therefore elute first. A chromatogram is obtained relating detector response with elution volume, where the size of the peak is proportional to the amount of polymer eluted. Detection of the polymer eluent is accomplished by refractive index or ultraviolet. In order to correlate eluent volume with molecular weight it is necessary to calibrate the column with standard polystyrene fractions of known molecular weight. Due to the calibration of the GPC columns by means of polystyrene standards the obtained molecular weight data for all other polymers are only relative.

A more sophisticated method to determine molecular weights is the so-called universal calibration. This method, based on the principle that  $\log([\eta]M)$

versus elution volume is a constant for all polymers, for a given column, temperature, solvent, and elution volume. In other words,

$$[\eta]_1 M_1 = [\eta]_2 M_2$$

where  $[\eta]_1$  and  $[\eta]_2$  are intrinsic viscosities of the standard and sample, respectively, and  $M_1$  and  $M_2$  are the molecular weight fractions of the standard and sample, respectively. The intrinsic viscosity can be determined with a special viscosity detector (commercialized by Viscotek, Houston, TX, USA) for a standard and an unknown sample and the equation is solved for  $M_2$  (molecular weight of the unknown sample).

Absolute  $M_w$  data can be obtained by using a light scattering detector. A beam of monochromatic polarized light (laser) is passed through the sample, and the intensity of the scattered light is measured at one or multiple angles after passing through a slit system and a second polarizer. The intensity of the scattered light ( $R_0$ ) is a function of the weight average molecular weight of the polymer ( $M_w$ ), the concentration ( $C$ ), and an optical constant ( $K$ ):

$$R_0 = K \cdot C \cdot M_w$$

The optical constant  $K$  depends on the refractive index (RI) of the polymer in the given solvent and is known for a few common polymers or can be determined from the signal of the RI detector (see above). Due to some given, not further explained boundary conditions, this method is suitable for polymers and synthetic fibers with an average molecular weight ( $M_w$ ) greater than  $100\,000 \text{ g mol}^{-1}$ .

### End Group Analysis

End group analysis is particularly suitable for condensation polymers in the molecular weight range of  $10\,000$ – $20\,000$ , such as polyesters and polyamides. These polymers contain titratable end groups that are distinct in character from the main chain. The carboxylic acid end groups of a polyester may be titrated by dissolution of the polymer in benzyl alcohol and the addition of sodium benzyolate as the base. The carboxyl or amino end groups of polyamides may be determined in phenol or *m*-cresol by titration with alkali or acid. The endpoint is determined in the presence of an indicator, or conductometrically.

### Osmometry

There are two principal methods of osmometry that are suitable for determining average molecular weights of polymers: membrane and vapor

pressure osmometry. While the first one is suitable for molecular weights between 50 000 and 2 million ( $\text{g mol}^{-1}$ ), the second one is applicable for 'short' polymeric chains below 40 000  $\text{g mol}^{-1}$ . Both methods deliver the absolute value of the number average molecular weight ( $M_n$ ).

In the first case, a solution of a polymer and the pure solvent are placed in compartments separated by a semipermeable membrane. The membrane allows diffusion of small solvent molecules, but restricts the larger polymer chains to one compartment only. Hence, a net diffusion of solvent takes place from the solvent side to the solution side until sufficient hydrostatic pressure develops that prevents further diffusion. This hydrostatic pressure is the osmotic pressure, which is related to molecular weight by the van't Hoff equation extrapolated to zero concentration:

$$\left\{ \frac{\pi}{C} \right\}_{C=0} = \frac{RT}{M_n} + A_2 C$$

where  $\pi$  is the osmotic pressure,  $C$  the concentration of polymer ( $\text{g l}^{-1}$ ),  $T$  the temperature (K),  $R$  the gas constant, and  $A_2$  the second virial coefficient (solvent dependent).

A plot of  $\pi/C$  versus  $C$  is a straight line of slope  $A_2$ , and  $\gamma$ -intercept equal to  $RT/M_n$ . The permeability of the membrane to low molecular weight chains renders membrane osmometry useful for polymer molecular weights greater than 50 000, while inaccuracy in the measurement of very small osmotic pressures sets the upper limit at 2 million.

The second method is based on the vapor pressure difference of pure solvent and a polymer solution. A sample of the solution and pure solvent are introduced into a temperature-controlled measuring chamber, which is saturated with solvent vapor. Since the vapor pressure of the solution is lower than that of the solvent, solvent vapor condenses on the solution sample causing its temperature to rise. This temperature difference ( $\Delta T$ ) can be measured for different concentrations ( $C$ ) of the polymer solution and  $1/M_n$  can be calculated according to the following formula:

$$\left\{ \frac{\Delta T}{KC} \right\} = \frac{1}{M_n} + A_2 C$$

$K$  is a measuring constant determined for a given solvent and temperature with an organic substance (e.g., benzoin) with exactly known molecular weight. A plot of  $(\Delta T/KC)$  versus  $C$  delivers  $1/M_n$  as the  $\gamma$ -axis intercept (slope  $A_2$ ).

## Viscometry

A routinely used method of molecular weight determination is to measure the intrinsic viscosity  $[\eta]$  in a suitable solvent, and then use a correlation based on the Mark-Houwink-Sakurada relationship:

$$[\eta] = KM_v^\alpha$$

where  $M_v$  is the viscosity average molecular weight, which lies between the corresponding values of  $M_w$  and  $M_n$ . The constants  $K$  and  $\alpha$  are the intercept and slope, respectively, the values of which have already been published for a wide range of polymers, solvents, and temperatures. Although this method does not provide an absolute determination of molecular weight, it is an extremely simple procedure and hence frequently utilized in commercial practice.

Viscosities are measured in dilute solutions (0–5 g per 100 ml) by monitoring the flow time of a certain volume of solution through a capillary of fixed length. The device used is called a capillary viscometer. Polymer solutions must be filtered carefully using microfilters, as dust and dirt particles significantly affect the flow time.

## Introduction

Thermal analysis (TA) can now be considered as a ‘mature science’, having been continuously developed over some 11 decades. In the last decade, there have been a variety of developments, not all associated with TA techniques. Those developments that have been associated with TA techniques relate to new methodologies, such as ‘temperature modulation’, ‘sample controlled regimes’, ‘online data analysis’, and ‘robotic operational regimes’. The major developments relate to the fields of application of TA techniques and the use of thermal methods in the kinetic analysis of chemical reactions. Hence, to write simply an ‘update’ presents a dilemma. This task has already been achieved via the recent publication of two books in the field, by Haines and by Brown. Further, any present coverage of the field needs to recognize that it has become increasingly difficult to differentiate between ‘TA’ and ‘calorimetry’ and many TA techniques can equally be classified as calorimetric techniques. Thermal methods of analysis have developed in accordance with the need to study the changes in the properties of a sample as a consequence of heating, whereas calorimetric methods measure such heat changes directly. TA and calorimetric techniques and the associated fields of application are uniquely complementary. The present review concentrates on developments associated with a wide range of TA techniques, with an emphasis on recent developments in applications of these techniques. In this context, it is the scope of the field overall that has developed very significantly, not only with respect to ‘techniques’ but also with respect to a range of associated features. These are highlighted here, in

addition to reviewing the developments associated with TA techniques.

## Revised Grouping of Techniques

For the purpose of the present review, TA techniques are grouped into four major categories: temperature modulated techniques, coupled techniques, sample controlled techniques, and less common techniques. ‘Modulation’ is probably the most significant development in terms of a ‘new’ TA technique. Modulation has had an impact on TA techniques similar to that of Fourier transform on infrared (IR) spectroscopy in that essentially, it has allowed a more complete analysis and a greater degree of refinement of a thermal event. Modulation has mainly been developed in conjunction with differential scanning calorimetry (DSC) to create a ‘new’ technique – temperature modulated (TM) DSC (TMDSC). Essentially, the use of TMDSC with appropriate frequencies and amplitudes of modulation allows separation of reversing processes, such as glass transitions, from nonreversing processes, such as relaxation endotherms or cure reactions. Further, baseline curvature on the cyclic signal is generally minimal – thus overcoming a major drawback of conventional DSC and making it easier to distinguish between baseline effects and real transitions. The overall resolution of TMDSC is higher than that of conventional DSC since with the former very low heating rates can be used. TMDSC has now become a major investigative technique in materials science and is used excessively in (synthetic) polymer science. The TM concept has also been applied to thermogravimetry (TMTG), thermomechanical analysis (TMTMA), dynamic mechanical analysis (TMDMA), and thermoelectrometry (TMTE) but to a lesser extent than to DSC. However, this family of ‘TM techniques’ deserves a separate review.

The second selected grouping of TA techniques is ‘coupled techniques’. These have also been traditionally grouped as ‘simultaneous TA techniques’,

although the range is now considerably greater than a combination of two TA techniques. With the coupled TA techniques, two or more types of measurement are made on the same sample at the same time. The benefits of such coupling are obvious. For a given material, it is unlikely that any single TA technique is able to provide a sufficiently comprehensive range of data for characterization purposes. Complementary data are usually required that may be obtained using another TA technique or via some other analytical process. With coupled TA techniques, the challenge is to correlate the individual sets of data obtained from the individual analysis systems that form the coupled technique. In simple terms, data that correlate precisely lead to a synergistic effect so that the total value of the information is greater than the sum of the parts, creating a 'multiplying effect'. However, although coupled systems are capable of excellent levels of precision and sensitivity, it is a fundamental principle that such systems do not perform the measurement in question as well as the dedicated separate units. Thus a compromise scenario prevails with the coupled TA systems. The earliest simultaneous TA system dates from 1955 and was developed by the Paulik brothers in Hungary. The instrument was called the 'derivatograph' and was essentially a combination of thermogravimetry (TG) and differential thermal analysis (DTA). The derivatograph has since been developed further to incorporate dilatometry and evolved gas analysis and has been used to pioneer the development of 'controlled rate methods' of TA. A range of commercial TG-DTA simultaneous TA systems is now available, and TG-DTA is the most widely used of the coupled TA techniques family. The 'coupling' can be further extended to analyzing the gases evolved during a thermal event – thereby creating an evolved gas analysis (EGA) system. This is achieved by coupling an STA system with a gas chromatograph and/or a mass spectrometer or, more recently, a Fourier transform IR (FTIR) spectrometer. Such highly sophisticated coupled systems are intrinsically very powerful 'complete analysis' systems.

It is also possible to couple TG with DSC to produce a simultaneous TG-DSC system. Apart from providing calorimetric data on a sample, subambient analysis is also possible with TG-DSC, which is especially useful for the study of systems containing moisture and other volatiles.

Hot-stage microscopy can be considered as a 'coupled TA technique' and has been widely applied. The technique involves observing a sample with a microscope as it is heated progressively on a 'hot-stage'. Such observations are often useful in the preliminary

interpretation of the thermal characteristics and behavior of materials by revealing the nature of the transition or reaction taking place. With particularly reactive materials, hot-stage microscopy can provide a preliminary 'thermal screening' that can be accommodated to prevent damage to a TG or DSC system in a subsequent detailed TA of such materials. Essentially, although a qualitative technique, hot-stage microscopy can reveal melting, bubbling, cracking, creeping, shrinking, swelling, decrepitation, and, significantly, interaction with crucible materials. In addition, the technique can reveal solid-solid transitions – particularly if associated with a color change and gas evolution with associated sample volume changes. It is also possible to combine TG, DTA, and DSC with microscopy – the latter systems have been particularly valuable for the investigation of coal samples, particularly in the determination of the pyrolysis and combustion characteristics of coal types.

Microscope hot-stages designed for transmitted light investigations and involving specially designed heating accessories have been used in conjunction with a FTIR spectrophotometer for studying physical and chemical changes in a heated sample. By using a hot-stage with a DSC cell incorporated, simultaneous DSC-FTIR is achieved. More flexibility can be achieved by using an IR microscope accessory to collect reflectance spectra from a sample contained in a DSC cell. Such a system is particularly useful for studying polymer curing phenomena and for studying structural changes occurring during glass transitions and melting.

X-ray diffraction (XRD) is particularly useful for the characterization of reaction intermediates and products in TA experiments. Coupling XRD to a TA technique potentially overcomes the difficulty of isolating the reaction intermediate or product from the TA system during a dynamic heating program – thereby avoiding 'time-lapse' phenomena and interactions with the prevailing atmosphere. Systems involving the coupling of TG with XRD and DSC with XRD have been devised and are particularly useful for a study of the thermal behavior of catalysts.

A relatively new TA technique, known as microthermal analysis ( $\mu$ -TA) can be considered as a coupled TA technique since usually two or more measurements are made simultaneously.  $\mu$ -TA combines the imaging capabilities of atomic force spectroscopy with a form of localized TA, and this technique offers nanotechnological TA applications.

The coupled TA techniques group consists not only of the commercial simultaneous TA systems but also a wide range of ingenious systems involving the coupling of TA systems with spectroscopic, optical, chromatographic, and a range of other analytical

techniques. Such coupled systems enhance very significantly the integrity of TA as a major analytical science, offering a diversity of application potential and a diversity of application range.

The third selected grouping of TA techniques is 'sample controlled techniques'. Sample controlled thermal analysis (SCTA) essentially overcomes the problems associated with linear heating rates in conventional TA. Linear heating rates cause significant temperature and pressure gradients in the sample. The judicious use of heating regimes that are modified in some manner by the reaction rate can greatly reduce these problems, giving enhanced resolution in analytical and characterization investigations. In conventional TA, the temperature of the sample follows some predetermined path as a function of time. In SCTA, it is a parameter of the sample that follows a predetermined path as a function of time, this being achieved by temperature variation of the applied heating program. Thus, SCTA represents a new paradigm in TA and was first introduced in 1989 by Rouquerol under the generic title 'Controlled Rate Thermal Analysis'. Essentially, in SCTA, it is the rate of mass loss of the sample material that is maintained constant during the applied temperature regime. An immediate advantage of the SCTA technique over conventional TA techniques is that the effect of material 'self-heating' is eliminated during the TA experiment. Over the last decade, a family of SCTA techniques has emerged. 'temperature-jump TG' and 'rate-jump TG', together with the very recent 'Hi-Res' TG<sup>TM</sup> and 'dynamic rate TG' – which are all members of this emerging SCTA family.

SCTA has many advantages over conventional TA techniques: SCTA data are less liable to contain artifacts due to inhomogeneous reactions within the sample matrix; SCTA generates superior kinetic data for the measured thermal event; SCTA offers defined preparative conditions for porous or finely divided solids such as coals – it is ideal for char preparation under defined conditions. Also, SCTA confines thermal events to occur within a narrow temperature range and clearly delineates the beginning and end of such events, thereby offering superior resolution of thermal events associated with materials. However, there is a major disadvantage of SCTA as compared with conventional TA techniques. The experimental time span required to complete an SCTA experiment is markedly increased over that for a conventional TA run due to the obvious fact that it is the thermal characteristics of the sample itself that control the time frame of the experiment rather than the operator.

Since SCTA usually provides improved control of the sample environment, it is frequently used as a method for preparing porous and finely divided

solids by thermal decomposition, specifically for use as catalysts. SCTA is particularly advantageous for the study of the reaction kinetics of materials. Temperature modulation is also being incorporated into SCTA to further enhance the unique capabilities and application range of these techniques.

The last group of TA techniques to be reviewed is that of 'nonbasic (or less common) techniques'. It is generally accepted that the basic TA techniques are TG, DTA, DSC, and the thermomechanical techniques, thermomechanical analysis (TMA) and DMTA. However, over the last decade, the range of TA techniques has widened considerably, and many of the so-called less common techniques have emerged into prominence. One such technique is thermomagnetometry. When a sample is placed in a magnetic field, it may experience either attractive or repulsive forces, the extent of which can be measured as an 'apparent' mass gain or a mass loss. Hence thermomagnetometry is particularly useful for analyzing the thermal behavior of paramagnetic and ferromagnetic materials. It has particular application to minerals and inorganic materials – particularly transition metal compounds. The apparatus for thermomagnetometry is the same as that for TG, with the addition of a magnet for producing a magnetic field around the sample. Temperature calibration of TG systems is effected by using 'magnetic standards' and is hence achieved by thermomagnetometry.

Emanation TA is another prominent less common TA technique. This technique involves the measurement of the release of (occluded) inert (usually) radioactive gas from a sample during the heating thereof. The rate of gas release reflects the changes that are occurring in the sample during the heating process and relate to the microstructure of the sample. The occluded gases are trapped at lattice imperfections, and these defects serve as both traps and diffusion pathways, and hence the migration of occluded gases in a solid effectively gives a three-dimensional defect map of the material under investigation.

Thermosonimetry (TS) and thermoacoustimetry have both attracted increased application in the last decade. In TS, sound waves emitted by a sample are measured as a function of temperature during heating of the sample. In thermoacoustimetry, the characteristics of imposed sound waves passing through a sample are measured as a function of temperature during heating of the sample. These techniques are particularly useful for detecting mechanical vibrations in a sample arising from dehydration, decomposition, melting, and solid–solid phase changes. TS data are usually used in combination with other thermoanalytical data (TG and DSC) to rationalize the thermal behavior of materials.

Thermoelectrometry embraces a small family of TA techniques that measure the electrical properties of a sample as a function of temperature. These techniques measure changes in conductance, capacitance, and dielectric properties as a function of temperature. The most prominent of these techniques is dielectric thermal analysis (DETA), which measures both the capacitance and the conductance of a sample as functions of time, temperature, and frequency. The capacitance is a measure of the ability of the sample to store charge, while the conductance is a measure of its ability to transfer charge. As for most TA techniques, it is the changes in these properties during thermal events in the sample that are of paramount interest rather than the absolute values of the properties themselves. DETA is particularly suited to the study of changes in molecular orientation during phase changes or chemical reactions or order-disorder crystal transitions. DETA is also useful for the resolution of multiple transitions in the solid state – particularly those associated with long chain and functional group motions in synthetic polymers.

Very recently, microwave thermal analysis (MWTa) has been enunciated. In MWTa, the sample is heated by microwave radiation, which has the advantage of providing direct molecular heating of the sample rather than via conduction or convection as in conventional heating regimes, and hence temperature gradients in the sample are minimized. Further, such uniform heating of the sample enhances the resolution of thermal events. Essentially, MWTa depends on changes in the dielectric properties of the sample, but because of its superior heating regime, it appears to have an illustrious future.

## Thermal Analysis Applications

Since TA techniques are conventionally applied to the study of the thermal behavior of materials in the solid state, it can be assumed that such techniques collectively have a major application in materials science. The thermal behavior of liquids can also be studied, but these require specialized variations of conventional TA techniques. Over the last decade, it is the development and extension of the application ranges of TA techniques that have been greater than the developments associated with the techniques *per se*. The range of application of TA techniques seems to be limited only by the sensitivity of the measurements and adaptation of the ‘problem’ to a ‘thermal solution’.

TA techniques can be used to study a wide variety of phenomena both physical and chemical in nature – such as melting and glass formation, solid-solid

phase changes, oxygen content, nonstoichiometry, structural defects, sintering and cracking, thermal expansion, dehydration, swelling, decomposition, heat capacity, sublimation, fusion, vaporization, linear and bulk deformations, reaction kinetics, surface morphology, and electrical properties of solids. As such, TA techniques inevitably have unlimited application.

With respect to the TA of individual compounds, as distinct from bulk materials, the thermal decomposition mechanisms of inorganic transition metal coordination compounds continues to be an expanding field of application – together with the application of thermal methods for deriving the kinetics of decomposition. In these contexts, such studies are becoming increasingly more creditable with the added characterization of reaction intermediates, evolved gaseous products, and final residues – usually achieved using EGA techniques for evolved gaseous products and IR and/or XRD for solid reaction intermediates and final residues. Such studies are usually correlated with the structures and thermal stabilities of metal complexes, particularly those of catalytic and biological activity.

With respect to organic compounds, those that are precursors to pharmaceuticals have attracted increasing interest from the viewpoint of their thermal properties, and TA techniques are used frequently in quality control procedures for such compounds. A wide variety of common and less common pharmaceuticals have also been investigated using a variety of thermal methods – mainly DSC and mainly in the context of purity determination. There is also potential for using TA techniques to identify pharmaceutical activity and for ‘shelf-life’ determinations.

In terms of (bulk) materials, the greatest use of TA techniques has been and continues to be focused on polymers. Techniques of particular prominence in this domain are DSC and the thermomechanical techniques. DSC is routinely used to study glass transitions in polymers together with curing phenomena of polymer blends. Thermomechanical methods are invaluable for the study of the mechanical properties of polymers in both the bulk form and in the form of fibers. New TA techniques such as  $\mu$ -TA will inevitably enhance and considerably refine these studies.

Minerals of great variety have been studied using TA techniques – particularly clay minerals and coal, lignite, and wood. Traditionally, the simultaneous methods have been applied in these cases, but increasingly, new methods such as sample controlled TA are becoming more prominent, particularly for studies of pyrolysis and combustion of coals. The rationale for using SCTA over conventional TA for the study of coal is simply related to overcoming the

problem of self-heating, which usually leads to premature ignition in coal combustion studies. Also, 'preparative SCTA' is available for 1 g samples – allowing the preparation of chars under precisely controlled conditions.

Progressive development of high-temperature DTA has allowed the thermal characterization of materials such as ceramics and studies of molten inorganic salts as stable nonaqueous solvents in synthetic chemistry and to some extent in industry. This latter field has attracted increased interest recently in terms of its potential 'green chemistry overtones'. Explosives, propellants, and pyrotechnics also form a major TA application area – particularly in terms of composition (phase diagrams) and thermochemical properties.

Other types of materials that lend themselves to TA investigation are electronic materials – with particular emphasis on the use of thermomechanical and thermoelectrical techniques. Heat capacity, conductivity, capacitance, dielectric phenomena, and structural morphology are all key features that can be studied using TA techniques.

There is much commercial interest in 'thin film' and 'nano' technologies, and these pose a new challenge for TA techniques since conventional TA deals with 'statistically averaged properties and phenomena'. However, with the advent of a range of 'modulated (temperature) techniques', micro sample sizes, and consequential rapid response times, the sensitivity of TA techniques generally is sufficiently enhanced to be able to address these immediate application challenges.

A wide range of biological materials ranging from hair and ancient papyri, to foodstuffs such as chocolate and edible oils and fats have been studied using TA techniques. The activity of biological materials in general is highly dependent upon temperature and frequently is confined to a narrow temperature range. The shelf-life of foodstuffs is obviously dependent on temperature, and the decay processes are delicately influenced by enzymatic action. It is these intriguing processes that can readily be studied using such techniques as DSC.

Finally, in terms of methodologies, TA techniques are routinely used for purity determination, heat capacity measurement, and kinetic analysis – the latter representing a major advance in the experimental reaction kinetics domain.

## Auxiliary Developments

It was emphasized (see Introduction) that the recent developments of TA techniques have been

comprehensively detailed in two recently published texts. A futuristic overview of further developments in the twenty-first century is given by a collection of papers in *Thermochimica Acta* (W. Hemminger, ed.). For completeness of the present overview of the field, some 'auxiliary (supplementary) developments' in TA are included here but are not further discussed in the subsequent four articles.

Thermal analysts operate under the acronym 'SCRAM' – 'sample', 'crucible', 'heating rate', 'atmosphere', and 'sample mass'. A thorough understanding of each of these components is critical if quality, reproducible results are to be obtained from a TA investigation. The art of TA is to relate the thermo-analytical data obtained directly to the sample under investigation. However, a myriad of experimental 'effects' affect such data, and hence, although thermal analytical techniques are generally regarded as 'easy to use', data correlation is most often not an easy task. Fortunately, over the last decade, sample, crucible, heating rate, atmosphere, and sample mass effects have been very effectively delineated, and a compendium of advice is now available as to how the majority of these effects can be overcome or avoided, so as to achieve thermoanalytical data of integrity and reliability.

Other 'technique related' developments include TA conducted under pressures greater than ambient. In high pressure DSC (HPDSC), the entire DSC cell can be pressurized to several megaPascals. HPDSC is useful in enhancing understanding of crystallization and melting of polymers and to determine the properties of materials produced under high pressure processing conditions such as injection molding. Another derivative of DSC is photo-DSC, in which samples can be irradiated with ultraviolet radiation to initiate reaction. This technique has particular application in polymer curing technology. Finally, in this context, robotic systems for handling multiple samples without direct operator intervention are available – particularly for use in DSC and quality control determinations. The sequence in which samples are handled and their individual treatments can be preselected and programmed, and the total data obtained are stored for subsequent analysis.

Any discussion of developments in TA would not be complete without reference to the concurrent development of software packages for TA data processing, and the availability of powerful spreadsheet packages, such as Microsoft Excel and Corel Quattro, has virtually removed any necessity for the writing of dedicated software. Databases for TA data and for kinetic analyses of TA results continue to develop. TA networks are proliferating.

Nomenclature in TA continues to be a controversial issue. The International Confederation of Thermal Analysis and Calorimetry (ICTAC) has essentially overseen developments in this domain over some four decades. However, practical nomenclature is determined by general acceptance, and a variety of factors affect this. The nomenclature recommendations released by Hemminger and Sarge in 2001, subsequent to widespread and intensive discussion with thermal analysts worldwide, have yet to be formally accepted by ICTAC. Likewise, modifications to the '*Recommendations for Reporting Thermal Analysis Data*' – as reported in the late 1960s and early 1970s – have yet to be approved by ICTAC. In short, developments on these issues have been severely curtailed by a lack of international agreement on the core principles.

Calibration of TA instrumentation and development of standards for calibration continue to be administered by ICTAC in conjunction with ASTM. The standardization Committee of ICTAC has certified a range of materials for temperature calibration of TA systems, and in addition, standards for calibration of 'mass' (known as 'Class M Standards') are available for this purpose. A range of certified reference materials are available for enthalpy calibration in DSC. Temperature calibration for TMA and dynamic mechanical analysis (DMA) is effected by using disks of pure metals (silver, aluminum, and tin) separated by alumina disks. Load or force calibration for DMA is a complex process involving the use of calibrated weights. Temperature calibration for DETA is effected by measuring the melting transition of benzoic acid and dielectric calibration is

simply achieved by measuring the dielectric constant of the empty cell. Developments in the area of calibration in TA involve increasing the range of calibration materials available, which involves exhaustive 'round-robin' assessment exercises of potential materials.

Developments in TA *per se* depend on the continuity of ICTAC and European Society for Thermal Analysis and Calorimetry conferences and the continuity of the publications on TA and calorimetry. Also, the future of TA (and calorimetry) depends on tertiary education institutions providing courses in these areas, so as to ensure a future supply of trained thermal scientists.

### Introduction

It has always been recognized that there is both a subtle difference and a synergy between 'thermal analysis' and 'calorimetry' and the associated groups of experimental techniques. There has been generations of interest in 'thermal events' as a means of articulating changes in materials and the consequences of such changes in terms of the laws of thermodynamics. The analysis of thermal events may be

approached in two different ways, which intrinsically overlap. Either the analysis is designed to measure specific properties of a material, such as heat capacity, enthalpy, entropy, free energy, with high precision and accuracy at predefined temperatures and conditions, or thermal properties may be studied over a temperature range using a controlled temperature program. Thus, calorimetry is the measurement of heat changes that occur during a process, whereas thermal analysis measures a property of a sample as a function of temperature. It is evident that calorimetry and thermal analysis are not synonymous terms. However, even with these simple definitions of both types of techniques, it is difficult to classify a

technique such as differential scanning calorimetry (DSC) either as a calorimetric or a thermal analysis technique, since in DSC heat changes are measured as a function of temperature and hence DSC clearly epitomizes the synergy between calorimetry and thermal analysis. The present article concentrates on the historical development of DSC and, more particularly, on the development of modulated temperature DSC (MTDSC), together with selected applications and future possible enhancements. Also, other temperature modulated thermal analysis techniques are briefly addressed.

## Development of DSC

Historically, DSC is a development of differential thermal analysis (DTA) and both techniques have a common origin in the measurement of temperature. The fundamental concept of both techniques is simple—to measure thermal changes in a sample relative to a thermally inert reference as both are subjected to a controlled temperature program. In classical DTA, the temperature difference between sample and reference is measured as a function of temperature: in classical DSC, the energy difference between sample and reference is measured as a function of temperature. Hence, DSC is simply ‘quantitative DTA’, or more precisely, DSC is a combination of DTA and adiabatic calorimetry. DSC is the more recent technique and was developed for quantitative calorimetric measurements over a wide temperature range from subambient to 1500°C. DTA is not appropriate for such precision measurements and has been progressively replaced by DSC, even for high-temperature measurements, as the major thermal analysis/calorimetric technique. DSC is a ‘differential calorimeter’ that achieves a continuous ‘power compensation’ between sample and reference.

Three major types of DSC have emerged that are classified as ‘scanning’, ‘isoperibol’, and ‘twin calorimetric’. The scanning type effects a power compensation between two separately heated calorimeters, the latter two types rely on measurement of the heat flux of two calorimeters subjected to a single heating system but differing in terms of the positions of the controlling temperature sensors. The heat-loss problem is minimized in DSC by the relatively short experimental time frame and the differential nature of the measurements reduces this phenomenon further. Thus, DSC precision is similar to that of the classical Nernst adiabatic calorimeter over the temperature range 150–450 K. However, the DSC operational range has now been effectively extended to 1500°C with concomitant precision and accuracy. DTA remains the technique of choice for the qualitative

characterization of materials and for thermal measurements in excess of 1500°C – at which temperatures severe design constraints are imposed on the equipment. Both DTA and DSC are most commonly applied to study the thermal properties of solids, but with more sophisticated experimental techniques liquids can also be studied. Sample sizes in the milligram range are typical together with experimental timeframes in minutes and these features have been paramount in the popularization of DSC coupled with its unrivaled application range.

The practical distinction between DTA and DSC is simply related to the nature of the signal output from the equipment. For DTA, this is proportional to the temperature difference between the sample and a thermally inert reference when both are subjected to the same temperature program. For DSC, this is proportional to the difference in thermal power between the sample and the inert reference. For both DTA and DSC, the classical temperature program is a linear temperature change with respect to time. However, more complex programs can be invoked by different heating and cooling rates with isothermal periods. A common example is ‘stepwise heating’, which can be used to detect the onset of melting under quasi-isothermal conditions. A most important innovation in terms of temperature programming has been to overlay the linear heating change with a regular modulation – thereby creating MTDSC. In the original form of the technique described by Reading in 1993, the modulation was sinusoidal. Other forms of modulation have since been introduced, such as square wave and saw-tooth. MTDSC has been shown to have many advantages over conventional DSC, including enhanced sensitivity and resolution and the ability in some cases to resolve multiple thermal events.

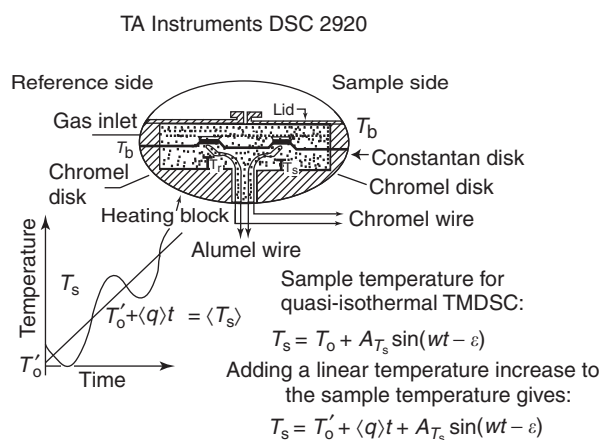

Three developments of calorimetry were thus combined in the last decade to dramatically enhance the capabilities of thermal analysis techniques and hence the study of the thermal properties of materials. These were the high precision of conventional adiabatic calorimetry, the speed of operation, and small sample size of DSC and the measurement of frequency dependence of thermal events and thus the MTDSC system evolved. ‘Modulation’ is perhaps the most significant development with respect to thermal analysis techniques paralleling in significance the ‘Fourier transform’ development of infrared spectroscopy.

## Development of MTDSC

The essential comparison between conventional DSC and MTDSC is shown schematically in **Figures 1** and **2**.

**Figure 1** Schematic of a classical heat flux DSC. (Reproduced with permission from Bernhard W (2000). Temperature modulated calorimetry in the 21st century. *Thermochimica Acta* 355: 43–57.)

**Figure 2** Schematic of a temperature modulated DSC. (Reproduced with permission from Bernhard W (2000) Temperature modulated calorimetry in the 21st century. *Thermochimica Acta* 355: 43–57; © Elsevier.)

In conventional DSC (**Figure 1**), the multiple temperature sensors average the calorimeter temperatures. In MTDSC (**Figure 2**), the linear heating program of conventional DSC is modulated by superimposing a periodic wave form of small amplitude on the linear temperature program. The most commonly applied wave form is a sine wave, as shown by the equations for sample temperature in **Figure 2**. Essentially, MTDSC provides periodic ‘heating’ and ‘cooling’ within each cycle but the overall effect is the same as in conventional DSC—a linear change in average temperature with time. The resultant heat flow signal is a composite of the response to a thermal event occurring in the sample and the response to the underlying heating program. Four-component signals thus derive from an MTDSC experiment, as shown schematically in **Figure 3** and

**Figure 3** The component output signals from TMDSC. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques & Applications*, p. 62. Amsterdam: Kluwer Academic.)

described as (i) the average or underlying signal, equivalent to DSC, (ii) the in-phase cyclic component, (iii) the out-of-phase component, (iv) the reversing component to the underlying heat flow, and (v) the nonreversing heat flow. Two of these components are interrelated – the reversing component (iv) is derived from multiplying the heat capacity of the sample by the heating rate and subtraction of (iv) from the underlying signal (i) gives (v) the nonreversing heat flow. Hence, in the simplest terms, MTDSC is a description of the heat flow into the sample resulting from the sinusoidal modulation of the temperature program. Two properties of the sample can be investigated by MTDSC – the heat capacity that is directly related to the ‘reversing component’ and a kinetically hindered thermal event that is related to the ‘nonreversing’ component. Conventional DSC provides only a measure of the total ‘heat flux’ into a sample as a function of temperature whereas MTDSC allows the heat capacity and kinetic components to be separated. However, the conditions of an MTDSC experiment are more critical than in conventional DSC since the selection of the period and amplitude of the modulation need to be selected in addition to the underlying heating rate. Sample size and the period of modulation influence the ability of the sample to follow the temperature modulation and hence the apparent value of the heat capacity. The underlying heating rate can be set to zero, in which case measurements are carried out under quasi-isothermal conditions.

Alternative modulation functions and data analysis procedures have been applied in MTDSC. Different instrument manufacturers have applied square wave or saw-tooth modulation, coupled with Fourier transform analysis methodologies. Alternative modulation functions provide some additional advantages – for example, a square wave function ensures that a steady state is achieved over an isothermal plateau since the signal during such a period is the nonreversing contribution. The amplitude provides a measure of the reversing signal. However, there are

some disadvantages of these alternative modulation functions, accuracy and resolution may be compromised since not all of the necessary data are made available.

There are many advantages of MTDSC over conventional DSC. Use of the former with appropriate frequencies and amplitudes allows separation of reversing processes, such as glass transitions, from nonreversing processes such as relaxation endotherms or cure processes. With MTDSC, baseline curvature of the cyclic signal is usually insignificant, thereby making it easier to distinguish between baseline effects and real transitions. The signal-to-noise ratio of the cyclic measurement of heat capacity is generally greater since all drift or noise at frequencies other than that of the modulation is ignored by the Fourier transform analysis. In general, in MTDSC, resolution of thermal events is improved because very low underlying heating rates are used.

## Applications of TMDSC

It is generally acknowledged that DSC is the preeminent thermal analysis technique and that it has progressively become the established technique for the study of the thermal behavior of polymeric materials. Conventional DSC links 'thermal power' to heat capacity and its integral to energy and entropy. Thus, DSC has primarily been applied to determine heat capacities of materials. Heat capacity is a primary thermodynamic parameter because of its intrinsic importance in materials characterization and its relationship to other parameters such as enthalpy, entropy, and Gibbs free energy. Conventional DSC is able to determine heat capacity to an uncertainty of 1–2%; MTDSC is able to measure heat capacity to an uncertainty of less than 1%, with reproducible reliability. Thus, fundamentally, MTDSC is able to measure thermodynamic quantities with uncertainties approaching those or equaling those of adiabatic calorimetry. It is the 'temperature modulation' feature of TMDSC that has confirmed this technique as the most versatile and most reliable of the thermal analysis techniques. Its versatility is further qualified by its ability to characterize the thermal behavior of materials without the need to have a detailed knowledge of the fundamental theoretical principles that underscore the basis of the technique. As for DSC, calibration of TMDSC is essential and this has presented a challenge. At present, the nematic to smectic-A transition in a cyanobiphenyl liquid crystal (80CB) has been suggested for calibration of TMDSC.

Five components of the MTDSC signal have been identified and these are conveniently shown by the separated MTDSC signal for a run on quenched

poly(ethylene terephthalate) (PET) in Figure 4. The difference in the Cp profiles corresponding to 'reversing Cp', 'kinetic Cp', and 'non-reversing Cp' are particularly striking and reveal the ability of MTDSC to provide 'complete' heat capacity characterization of a polymer sample.

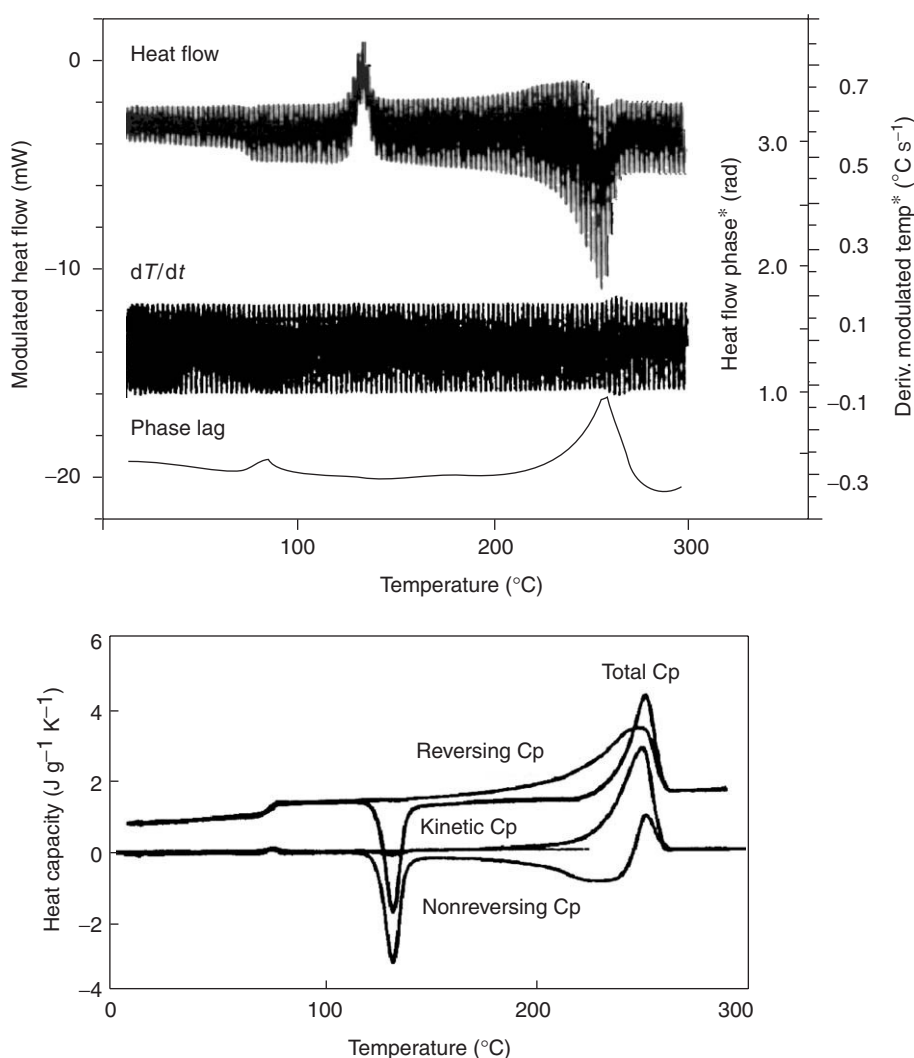

MTDSC has major advantages over conventional DSC in terms of differentiating overlapping thermal events. Figure 5 shows the MTDSC curves for a PET-acrylonitrile/butadiene/styrene (PET-ABS) blend. The total heat flow profile for the blend and its separation into the reversing and nonreversing components is shown. The glass transition temperature for PET is around 65°C and that for ABS is at 105°C. Crystallization of PET is revealed as a peak in the nonreversing curve and is also around 105°C, which would mask the glass transition of ABS in conventional DSC.

A more detailed theoretical treatment of the relationship between heat capacity and the reversing component of MTDSC shows that a 'reversing time correction factor' has to be included, which depends on mass and sample. By using multiple frequencies for modulation, the required correction can be made in a single MTDSC run, which further indicates the supremacy of TMDSC in heat capacity measurements.

Applications of TMDSC in general rely on the enhanced precision of the technique compared to conventional DSC as attained by the maintenance of a steady state and a negligible temperature gradient within the sample throughout the run and hence it is possible to measure heat capacity quasi-isothermally. In order to achieve the highest precision in TMDSC, the theory of the technique indicates that a high heating rate should be applied together with a large sample mass. These conditions lead to rapid analysis of large samples and give a further advantageous feature of DSC.

TMDSC is routinely applied to determine glass transitions of polymers. TMDSC offers quantitative investigation of polymer glass transitions as a function of 'thermal history', since glass transition kinetics vary with the enthalpy of the glass. Further, the ability of MTDSC to separate reversing and nonreversing processes during phase transitions offers quantitative investigation of cold crystallization and melting with superheating transitions. MTDSC therefore offers unparalleled opportunities for the quantitative analysis of the thermal properties and thermal behavior of materials, particularly synthetic polymeric materials.

A summary selection of recent specific applications of TMDSC is given here to illustrate the present and future potentials of the technique. Reactions involving partial diffusion can be studied by TMDSC such as

**Figure 4** Component TMDSC signals for a quenched PET sample. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques & Applications*, p. 63. Amsterdam: Kluwer Academic.)

epoxy resin curing. The glass transition temperature is measured as a function of the conversion fraction. TMDSC is able to separate the glass transition and the melting transition in interpenetrating polymer networks prepared by in situ copolymerization. Additionally, an estimate of the degree of crosslinking in the copolymer is possible from the composite thermal data together with an estimate of the glass transition temperature of the copolymer phase.

The Wunderlich ATHAS laboratory has investigated other types of modulation, including 'saw-tooth' and 'square' and has shown that such modulations are likely to be incorporated into future generations of TMDSC systems for enhanced precision of measurement of heat capacity and glass transitions.

Numerous TMDSC applications were presented at the 8th European Symposium on Thermal Analysis & Calorimetry (ESTAC 8) in Barcelona, 2002. TMDSC

has been applied to study the morphology and recrystallization kinetics of nickel sulfide. Such information is of significance in understanding the failure of toughened glass panels when subjected to external stresses. TMDSC is shown to be ideal for rationalizing the melting behavior of polytetrahydrofurans and their blends. The PTHF oligomer shows two endothermic peaks – the lower peak shows temperature dependence on molar mass whereas the higher peak is independent of molecular mass of the polymer. The order–disorder transition behavior of triblock copolymer gels, swollen with paraffinic oils, has been studied by TMDSC. The order–disorder transition temperature of these gels is detected, reproducibly, as an abrupt change in heat capacity of the sample and is dependent on the polymer content of the gel and on the molecular weight of the oil. Thus, TMDSC assists in the understanding of the

**Figure 5** TMDSC curves for a PET-ABS blend. (Haines PJ (ed.) (2002) *Principles of Thermal Analysis & Calorimetry*. Cambridge: Royal Society of Chemistry; reproduced by permission of The Royal Society of Chemistry.)

mechanism of order-disorder transitions in triblock copolymers swollen with solvents. TMDSC has been applied to study 'intelligent' polymer systems, which show major changes in properties with small physical or chemical stimuli. The kinetics of 'demixing' (shrinking) and 'remixing' (swelling) are important considerations in possible applications of these systems. In this context, it is shown that TMDSC is ideal for the characterization of the kinetics of phase separation in partially miscible polymer blends and polymer solutions. 'Mixing/demixing' phenomena are manifested as large excess contributions to the apparent heat capacity signal of the system on the time scale of the temperature modulation that enable the real-time monitoring of demixing, remixing, and vitrification processes occurring. TMDSC thus allows investigation of nanoscale miscibility phenomena in water-soluble polymers and related hydrogels. TMDSC has been shown to be valuable for studying the deconvolution of 'nonreversing' and 'reversing' heat flow effects in reacting polymer systems. TMDSC has been further extended to study temperature-induced phase separation in polyethylene/polyethersulfone blends. TMDSC has also been applied to model the effect of additives on the cure kinetics of epoxy resins and for in situ detection of reaction-induced phase separation. The cure temperature is crucial in determining the final, phase-separated morphology and impact properties of such resins. TMDSC, in conjunction with TG, has been applied to characterize elastomers. From the component pyrolysis temperatures, TMDSC can be used to quantitatively determine the individual polymer

compositions. TMDSC has also been applied to study the vitrification, devitrification, and dielectric relaxations associated with the nonisothermal curing of an epoxy-amine system. Such systems are characterized by continuous heating transformation cure diagrams, which are readily obtained by TMDSC. The cold crystallization and melting of PET and poly(ethylene-2,6-naphthalene dicarboxylate) have been studied by TMDSC with a net zero heating rate. This application is typical of routine TMDSC analysis of synthetic polymer systems. TMDSC has also been applied to study high-temperature polymeric materials, such as bismaleimide resins, which find extensive use as light-weight fiber-reinforced structural composites and electrical insulators. Finally, maximum precision in TMDSC is obtained with very slow underlying heating rates that allow an adequate number of temperature modulations over a region of changing heat capacity such as a transition region. This condition has recently been achieved by the new DSC cell and 'Tzero' technology, developed by TA instruments (USA). In this new system, the thermal capacitance and resistance of the DSC measuring system are effectively eliminated and this feature, coupled with overall improved temperature control capabilities, has made much shorter modulation periods practical. Hence, 'fast TMDSC' is now a reality.

It is apparent from the rapid routine adoption of DSC for the characterization of materials, particularly synthetic polymers, that TMDSC with its additional advantages, is currently recognized as the most versatile analytical technique in materials science. It is inevitable that applications of TMDSC will dominate the thermal analysis and calorimetry literature in the current century.

## Other Temperature Modulated Thermal Analysis Techniques

In terms of 'modulated thermal analysis techniques', TMDSC clearly dominates the group. However, there is limited literature on temperature modulated thermogravimetric analysis (TMTGA) and temperature modulated thermomechanical analysis (TMTMA). Modulation principles have been applied to some less common thermal analysis techniques such as DMA and thermally stimulated current analysis and these developments will be briefly addressed here. It appears that the major development in thermal analysis in the next decade will be in the temperature modulated domain.

TMTGA has been developed by TA Instruments and essentially provides a kinetic analysis of solid-state

decomposition processes of inorganic salts, such as carbonates, sulfates, and oxalates. Thermogravimetry has long been applied to study the kinetics of a wide range of decomposition processes—it appears that TMTGA provides a refinement and an extension of this application. In TMTGA, a sinusoidal temperature modulation is superimposed on the linear heating rate program used in traditional TGA. This modulated temperature stimulus results in an oscillatory response in the rate of mass loss, deconvolution of which via a real-time discrete Fourier transform gives the relevant kinetic parameters of the reaction under study. While many materials decompose in a single step, others decompose in a stepwise manner, involving sequential mass losses. These stepwise mass losses may be widely separated in temperature, which leads to long experimental TMTGA times. To overcome the latter disadvantage, TA Instruments have also developed dynamic rate ‘High-Res’ TG<sup>TM</sup> TGA, which essentially involves rapid heating during thermal events and slow heating between them and is thus a sample controlled thermal analysis technique. This technique, in conjunction with TMTGA, provides high resolution of thermal events with short experimental times. A further advantage of TMTGA is that the reaction activation energy is determined as a function of the extent of reaction and hence no prior knowledge of the form of the relevant rate equation is required. The variation of activation energy is indicative of the reaction decomposition mechanism. Thus, for a single reaction mechanism, the associated activation energy shows no variation with the percentage conversion, whereas variation of activation energy with extent of reaction is indicative of ‘*n*th order’ processes. In addition to traditional thermal decomposition studies of materials, TMTGA has considerable promise for the study of metal oxidation and coal combustion processes, for which reliable kinetic data have considerable commercial value. It is also particularly applicable to study autocatalytic decomposition processes of commercial polymers such as polystyrene and polytetrafluoroethylene. Thus, ‘temperature modulation’ of TGA has produced a similar ‘revolution’ in thermogravimetry compatible with ‘temperature modulation’ of DSC and has certainly qualified thermogravimetry as the major technique for derivation of the reaction kinetics of materials decomposition.

Thermomagnetometry is directly related to thermogravimetry and involves heating the sample in a constant applied magnetic field. Magnetic transformations in the sample are manifested as ‘apparent’ mass changes. Temperature modulated thermomagnetometry has been applied to study the nanophase crystallization characteristics of amorphous

alloys. Nanocrystalline magnetic alloys are obtained by partial devitrification of the amorphous precursor and have ‘soft’ magnetic properties with high saturation magnetic flux density and high permeability. The nanocrystalline phase is obtained from the amorphous precursor under controlled annealing conditions. The ‘controlled conditions’ and the study of ‘soft magnetic properties’ are provided by TMTM and hence this technique has a very promising future in alloy nanotechnology.

In the same way that applying a temperature modulation to DSC can separate thermally reversing thermal events such as a glass transition from thermally nonreversing events such as crystallization and curing, these principles can be similarly applied to thermalmechanical analysis (TMA). TMTMA allows for the separation of reversible dimensional changes due to expansion from irreversible dimensional changes such as stress relaxation and creep. As for TMA, measurements can be made under tension (films and fibers) or under compression (rods and blocks). Similarly, temperature modulated DMA has been applied to study the reversible melting of polymers. Essentially, temperature modulation of thermomechanical techniques provides for enhanced resolution of polymeric transformations and hence has a promising future in this domain.

Finally, temperature modulated thermally stimulated current analysis has been applied to study dielectric materials via the separation of reversible pyroelectric effects from nonreversing thermally stimulated discharges.

### Introduction

As the number of thermal analysis (TA) techniques increased and the application field widened, it became apparent that for a detailed investigation of materials, it is improbable that any single TA technique is able to provide sufficient information to characterize its thermal behavior. Complementary information is usually necessary, which may be derived from another TA technique or from a supplementary analytical technique. The type of analytical technique differentiates between ‘simultaneous thermal analysis (STA) techniques’ and ‘coupled techniques’. By inference, the latter group includes a wider range of techniques than does the former group. The challenge for both groups is to be able to correlate the data from the individual analyses. Essentially, STA is a combination of (usually) two TA techniques such as thermogravimetric analysis (TGA)–differential thermal analysis (DTA), TGA–differential scanning calorimetry (DSC), and involves measurements of two thermal properties on the same sample subjected to the same temperature program. Each of the two thermal properties may be monitored continuously or they may be monitored in a repetitive sequence to allow for the requirements of data capture. Coupled techniques include the ‘evolved gas analysis’ (EGA) group of techniques

and involve the ‘coupling’ of two different types of analytical techniques, such as TGA–gas chromatography (GC) or TGA–mass spectrometry (MS). However, with the introduction of new thermoanalytical techniques and the refinement of traditional analytical techniques, the ‘simultaneous’ group and the ‘coupled’ group have both expanded considerably and these are now generally regarded as powerful ‘complete’ analytical systems for the investigation of a wide range of materials.

A simple differentiation between ‘simultaneous’ and ‘coupled’ techniques is that for the former both techniques are TA techniques, whereas for the latter only one of the two is a TA technique. However, the identification of two groups derived from combining two analytical techniques has significance beyond that of semantics. In STA, it is necessary to refine the term ‘simultaneous’ and to differentiate it from two other types of measurement – ‘parallel’, in which different portions of a sample are examined using different techniques and ‘concurrent’, in which different portions of the same sample are contained in different crucibles in a single furnace and are hence subjected to a common temperature program. There are advantages of STA over ‘parallel’ and ‘concurrent’ simultaneous measurements. Fundamentally, it is difficult to correlate results obtained on different portions of a sample with different techniques due to ‘sample’ and ‘instrument’ factors, whereas, in general, results obtained on the same sample by two TA techniques simultaneously are reproducible. In general, STA may be viewed as yielding data that are more significant than the sum of the two sets of

### Introduction

As the number of thermal analysis (TA) techniques increased and the application field widened, it became apparent that for a detailed investigation of materials, it is improbable that any single TA technique is able to provide sufficient information to characterize its thermal behavior. Complementary information is usually necessary, which may be derived from another TA technique or from a supplementary analytical technique. The type of analytical technique differentiates between ‘simultaneous thermal analysis (STA) techniques’ and ‘coupled techniques’. By inference, the latter group includes a wider range of techniques than does the former group. The challenge for both groups is to be able to correlate the data from the individual analyses. Essentially, STA is a combination of (usually) two TA techniques such as thermogravimetric analysis (TGA)–differential thermal analysis (DTA), TGA–differential scanning calorimetry (DSC), and involves measurements of two thermal properties on the same sample subjected to the same temperature program. Each of the two thermal properties may be monitored continuously or they may be monitored in a repetitive sequence to allow for the requirements of data capture. Coupled techniques include the ‘evolved gas analysis’ (EGA) group of techniques

and involve the ‘coupling’ of two different types of analytical techniques, such as TGA–gas chromatography (GC) or TGA–mass spectrometry (MS). However, with the introduction of new thermoanalytical techniques and the refinement of traditional analytical techniques, the ‘simultaneous’ group and the ‘coupled’ group have both expanded considerably and these are now generally regarded as powerful ‘complete’ analytical systems for the investigation of a wide range of materials.

A simple differentiation between ‘simultaneous’ and ‘coupled’ techniques is that for the former both techniques are TA techniques, whereas for the latter only one of the two is a TA technique. However, the identification of two groups derived from combining two analytical techniques has significance beyond that of semantics. In STA, it is necessary to refine the term ‘simultaneous’ and to differentiate it from two other types of measurement – ‘parallel’, in which different portions of a sample are examined using different techniques and ‘concurrent’, in which different portions of the same sample are contained in different crucibles in a single furnace and are hence subjected to a common temperature program. There are advantages of STA over ‘parallel’ and ‘concurrent’ simultaneous measurements. Fundamentally, it is difficult to correlate results obtained on different portions of a sample with different techniques due to ‘sample’ and ‘instrument’ factors, whereas, in general, results obtained on the same sample by two TA techniques simultaneously are reproducible. In general, STA may be viewed as yielding data that are more significant than the sum of the two sets of

data – a synergistic effect operates. This effect is readily apparent – TGA can only detect thermal events associated with a mass change – so a phase change such as ‘melting’ is not detected by this technique; however, melting can readily be detected by DTA. Thus, a combination of TGA and DTA shows no sample mass change associated with the endothermic (melting) DTA peak. However, DTA (or DSC) alone is unable to differentiate between types of sample enthalpy changes such as melting and decomposition. A combination of TGA and DTA (or DSC) is able to produce such differentiation, since ‘decomposition’ is associated with a mass change. Thus, STA is able to characterize a thermal event both qualitatively and quantitatively. The synergistic effect operating in STA is readily apparent from an examination of a material that melts with decomposition. The overall thermal event is readily characterized by STA, whereas TGA and DTA alone can only partially define such a transformation. Other obvious advantages of STA are ‘time saving’ (only need to do one experiment instead of two), ‘sample saving’ (only requires one portion of a sample instead of two), and ‘capital cost savings’ (only needs one TA instrument instead of two). However, generally, the sensitivity of individual TA techniques is decreased on combination due to essential compromises in instrumental design. Also, it is technically difficult to combine TG with DSC primarily because of the limited temperature range of DSC and its associated sophisticated temperature programming capabilities. Essentially, the major advantage of STA is associated directly with the unambiguous correlation of two sets of TA information on the same sample subjected to the same temperature regime. This feature promotes STA for the examination of complex materials such as coals, minerals, ceramics, pharmaceuticals, and commercial polymers.

Other STA techniques include the thermoptometry systems, such as the combination of TGA with an optical microscope to give a thermomicroscopy system – of which there are many variants. Thermomicroscopy systems allow visual observation of thermal events such as melting, bubbling, creeping, shrinking, swelling, decrepitation, and corrosion. DSC and DTA can also be combined with microscopy. X-ray techniques, such as X-ray diffraction (XRD), have also been combined with TA techniques, particularly to identify solid reaction intermediates and products. The most promising recent development with respect to simultaneous techniques is micro-thermal analysis ( $\mu$ -TA) and this has unrivalled potential for using TA to investigate materials at the nanosubmicroscopic level.

Coupled techniques have attained enhanced popularity as quantitative EGA systems. Essentially, the

coupled analytical technique characterizes the products evolved from a TA investigation. The initial coupled technique was evolved gas detection (EGD) and involved the coupling of a TGA to a gas chromatograph. However, it was recognized that essentially EGD was a qualitative technique and that the ultimate aim of coupled techniques is to provide complete information on a thermal event by not only identifying mass changes and temperatures of thermal transitions but also by characterizing the products of a thermal decomposition. With the coupling of TGA to mass spectrometry, this primary aim was achieved and EGA systems rapidly developed. Thus, EGA provides an opportunity to obtain ‘online’ chemical information associated with a thermal event. EGA has been accorded the title of ‘a complete analysis system’ by instrument manufacturers in recognition of its primary features. However, advances in EGA depend very significantly on the many technical problems associated with the ‘coupling’ of the two techniques in question and this feature is perhaps a limiting factor on the range of EGA applications. It is certainly a primary technique for the characterization of the thermal behavior of materials such as coals and commercial polymers. Other types of analytical techniques may be coupled to a TA technique, such as a Fourier transform infrared (FTIR) spectrophotometer to give the EGA technique TGA–FTIR. A gas chromatograph may also be interfaced with this system to give TGA–GC–FTIR.

The present article focuses primarily on the most significant coupled techniques that envelope and extend the traditional STA techniques. The basic principles of these techniques will be described together with a range of associated applications.

## Simultaneous Thermal Analysis Techniques

The pioneering STA system was the ‘derivatograph’, developed by J Paulik and F Paulik in 1955. It involved the direct combination of TG with DTA to give TG–DTA. Over subsequent decades, the derivatograph was developed to incorporate dilatometry and EGA. Over the last decade, controlled rate methods were also included, thus making the derivatograph the most versatile of the STA techniques. STA instruments involve the mounting of a DTA head onto the thermobalance suspension or rise rod, which is connected directly to a microbalance. Modern TG–DTA instruments are capable of a resolution of the order of 1  $\mu$ g with sample masses ranging from 5 to 100 mg. As for all TA techniques, temperature calibration is essential for STA, particularly when

the TG data are used for kinetic analysis of reactions. Temperature calibration of an STA is conveniently achieved by reference to the melting temperatures of pure metals. The TG mass loss scale is usually calibrated by using the ICTAC Curie Point (magnetic) standards. As previously noted, STA has many advantages over independent TG and DTA. Since sample mass is continuously monitored, DTA peak measurements can be directly correlated with sample mass after allowing for lower temperature mass losses such as dehydration. Also, peak area measurements can be correlated with single process thermal events in cases where the corresponding TG curves show that no decomposition or sublimation is taking place. This is particularly advantageous in the high-temperature studies of alloys and ceramics.

STA has been widely used in coal studies. Combustion of coal is highly sensitive to experimental conditions and TA experiments are usually associated with low reproducibility. STA markedly enhances coal combustion reproducibility and this feature accounts for its popularity as an analytical technique for studies of the thermal behavior of coals. In simple terms, the initial drying process of a coal can easily be separated from the subsequent oxidation, which in STA can be assigned directly to a 'dry weight'.

Simultaneous DTA can often provide an explanation of unusual features of a TG curve. For example, abrupt changes in the rate of mass loss can occur simultaneously with sample melting or, conversely, the TG curve may show that melting occurs with decomposition. The latter feature is particularly prevalent with organic compounds. The rate of reaction in a solid-state system or the rate of a solid-gas reaction may be associated with the intermediate fluid phase, the formation of which is revealed by an arrest of mass loss in the TG profile and the corresponding temperature range may be determined from the simultaneous DTA profile. Irregular sharp features on a TG curve due to 'bubbling' in a viscous melt are usually seen as sharp spikes on the corresponding DTA curve. Thus, STA has major advantages in the characterization of melting processes and this explains its value in widespread TA studies of commercial polymer systems. Phase diagrams for alloy systems are readily derived by high-temperature STA studies and 'molten solvent' applications have been widely studied by STA, using specially designed stainless steel instrumental accessories. A further major application of STA has been directed at catalyst composition and activity – particularly low-temperature catalytic activity and the associated economic consequences.

Over the last decade, DSC has progressively replaced DTA as the major TA technique and hence

STA has been extended to include TG–DSC. However, the complexity of power-compensated DSC sensors and their operation to a relatively restricted temperature range has precluded combination of power-compensated DSC with TG. Hence, TG–DSC involves the combination of TG with heat-flux DSC. The advantages of TG–DSC include all those associated with TG–DTA with the addition of quantitative calorimetric data on thermal events. Also, DSC is particularly suitable for the study of 'subambient' thermal events and this is particularly important for the study of systems containing moisture or other volatiles. Hence, subambient TG–DSC can be applied to study the multiple solid-state phase transitions in ammonium nitrate. It is known that traces of moisture can influence these transitions both in terms of 'extent' and 'temperature' – STA is able to determine the moisture content associated with each thermal event and hence an unambiguous TA of ammonium nitrate is achieved. A further application of TG–DSC is the determination of vaporization enthalpies of liquids. These are generally difficult to obtain by other methods due to 'partial' or 'incomplete' vaporization. In TG–DSC, the extent of vaporization is determined directly from the TG profile and the corresponding vaporization energy is obtained from the area of the associated DSC endotherm. For this type of investigation, the sample is sealed in a container with a small pin-hole such that a smooth effusion of vapor is achieved, corresponding to a constant rate of mass loss. Calibration of the STA system is necessary with a sample of well-defined vaporization enthalpy. TG–DSC can also be applied to determine sublimation enthalpies – using benzoic acid or ferrocene as calibration standard. A notable application in this context is the determination of the sublimation enthalpies of volatile coordination compounds, particularly those of the later transition metals. In terms of studying the volatility of (toxic) organic compounds, STA has a promising future as a valuable technique in promoting 'green chemistry'.

Thermooptometry is the generic term relating to the observation or measurement of an optical property of a material as a function of temperature. Samples can be viewed by reflectance or by transmission and the light intensity in each case can be measured by a photocell, thereby quantifying the technique. The earliest system was the well-known hot-stage microscope, which has had widespread application and is still used extensively. The modern equivalent is a thermomicroscopy system, which consists of a microscope with a hot and/or cold stage, a sample holder, gaseous atmosphere control (including vacuum), light sources, and a system for processing

and recording visual observations together with the sample temperature. Visual observation of a sample during a thermal event is often useful in characterizing the event in terms of its 'completeness', shrinkage, swelling, creeping, bubbling, cracking, and extent of surface activity. Further, many solid-solid transitions are detectable by a color change or volume change – which can be monitored by thermomicroscopy. Hot-stage microscopy has been used to determine the ignition temperature of pyrotechnic compositions. Modifications of the basic system were necessary, including mounting the sample between two microscope cover glasses that rested on a heating block within an atmosphere-controlled chamber. The block contained a sapphire window for light transmission and a platinum resistance thermometer was used for measurement of sample temperature and for the control of the heating/cooling program. The transmitted light intensity was measured by a silicon photodetector. A subambient facility further extends the operating temperature range of hot-stage microscopy systems from  $-180^{\circ}\text{C}$  to  $600^{\circ}\text{C}$ .

Simultaneous thermomicroscopy/thermal analysis techniques have been developed. A TG-thermomicroscopy system has been developed for a study of the pyrolysis and combustion of coals. The microscope is combined with a video camera to continuously monitor the thermal events involved and the sample holder for microscopy is attached to the microbalance by an aluminum oxide capillary. Events such as partial fusion, swelling, and internal structural changes associated with coal can be observed microscopically and correlated directly with noted associated mass losses. The system is particularly suitable for coal analysis involving rapid heating rates and atmosphere switching.

Conventional DSC has been modified to carry out simultaneous measurements of the intensity of light reflected from the sample. Changes in sample surface characteristics may not be associated with measurable enthalpy changes but may be manifested by changes in reflectance. A binocular microscope was employed so that one eyepiece photographs the actual appearance of the sample while the photodetector is the other eyepiece. Changes in the intensity of the reflected light are cumulative so that the net curves recorded are related to DSC curves as integral to derivative.

Other spectroscopic techniques have been combined with TA techniques. Thermomicroscopy has been combined with FTIR spectrophotometry and by using a hot stage with a DSC cell incorporated, simultaneous DSC-FTIR is achieved. However, with these later combinations, thin sample films are required that give poor DSC sensitivity. More flexibility

can be obtained by using an IR microscope accessory to collect reflectance spectra from a sample mounted in a DSC cell. DSC-FTIR is particularly suitable for studying curing processes in an amine-cured epoxy material and to study changes in poly(ethylene)terephthalate (PET) through its glass transition and melting regions.

TG, DTA, and DSC have been combined with XRD to give enhanced thermooptometry techniques. These simultaneous techniques are particularly advantageous for the investigation of the thermal behavior of materials in the solid state. A TG may be coupled with an XRD by mounting a top-loading thermobalance onto a diffractometer such that the sample is coincident with the X-ray beam. Simultaneous TG-XRD has been used to investigate the complex series of thermal events associated with the hydrogen reduction of tungstic oxide. The associated TG curve is featureless and difficult to interpret but the XRD spectra indicate that the reduction proceeds via the production of many intermediate tungsten-oxygen phases and through two tungsten modifications.

XRD has also been coupled to a DSC and the resulting simultaneous system is particularly suited to the study of catalyst regeneration by indicating the nature of the intermediate phases and the energy transformations involved. However, a difficulty with this technique is that XRD requires slow temperature scans to maximize sensitivity, which decrease DSC sensitivity. This problem appears solvable by using a high-intensity synchrotron X-ray source. The latter system appears particularly suitable for a TA study of liquid crystals.

Hemminger and Felder-Casagrande have comprehensively reviewed the wide range of applications of thermooptometry, which range from an investigation of the hydration/dehydration of gypsum to form the hemi-hydrate 'plaster of paris' to the nucleation of graphite on the surfaces of natural diamond. Thermomicroscopy is also particularly valuable for the investigation of the thermal behavior of solid solutions, liquid crystals, explosives, and pharmaceuticals. The singular advantage of the simultaneous technique involved in these investigations is its ability to characterize a thermal transition, not only in terms of a mass or energy change, but also spectroscopically. It is this correlation that unambiguously defines the thermal behavior of the material under investigation.

A recent addition to the family of STA techniques is micro-thermal analysis ( $\mu$ -TA). This technique combines the imaging capabilities of atomic force microscopy (AFM) with a form of 'localized' TA and has the capability of imaging thermal behavior of

solids over an area of a few microns.  $\mu$ -TA has major potential as an analytical technique in the nanotechnology era. The sensor is a very fine, pointed platinum wire mounted on the tip of an AFM probe. The sample (or sample region) is heated at a linear rate by passing a current through the wire and the resistance of the wire sensor is used simultaneously to measure the sample temperature. Since the sensor has a small thermal mass, heating rates in excess of  $20^{\circ}\text{C min}^{-1}$  can be used. The enhanced imaging capabilities of the AFM are used to map the surface area of interest as a function of temperature. The use of a controlled temperature (microscope) stage allows the entire sample to be heated or cooled and a thermal probe is then not necessary. Standard AFM contact or non-contact probes can then be used to obtain surface images of high resolution.

There are several 'forms' of  $\mu$ -TA. Micro-DTA involves comparison of the temperature difference of the sample with respect to a thermally inert reference material, as in normal DTA. If the probe is loaded with a small force, microthermomechanical analysis results. The  $\mu$ -TA configuration can be used for rapid pyrolysis of a small area of the sample and the evolved gases can be analyzed 'online' by a GC-MS system. This mode is particularly valuable for the compositional analysis of synthetic polymers. Sinusoidal temperature programs have also been applied in  $\mu$ -TA leading to temperature modulated  $\mu$ -TA.

$\mu$ -TA is more difficult to calibrate than macro-TA techniques. Temperature calibration of  $\mu$ -TA is achieved by using powdered organic compounds of well-defined melting point, such as biphenyl or benzoic acid. Pure metals cannot be used for this purpose because the calibrant comes into direct contact with the platinum wire sensor. With organic calibrant materials, the probe is easily cleaned by heating in air. For synthetic polymers, a suitable calibrant is PET.

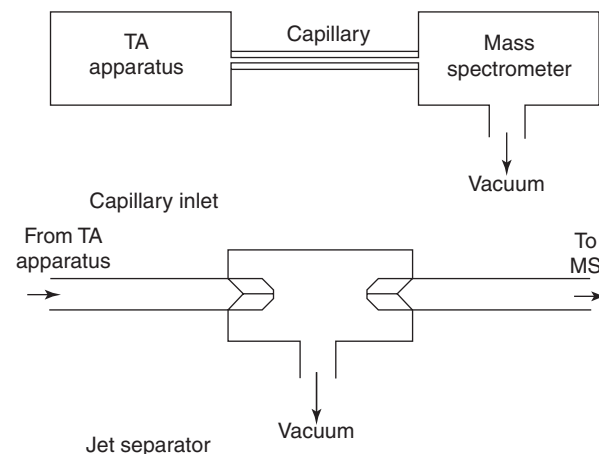

$\mu$ -TA offers a new analytical dimension in the materials and surface sciences. Typical applications relate to synthetic polymers, pharmaceuticals, microelectronics, cellular biology, and multilayered systems such as emulsion paints.

## Coupled Thermal Analysis Techniques

The coupled TA techniques specifically relate to EGA. Essentially, EGA characterizes the gases evolved during a TA investigation and hence augments the total information obtained. The most common EGA techniques are the coupling of TG and/or DTA with GC and/or MS. The coupling relies on a flowing purge gas stream through the system such that the evolved gases are swept into the

coupled analysis system. The most comprehensive EGA system is a TG-DTA-GC-MS, which combines the advantages of STA with the gas separation ability of GC and the identification ability of MS. TG-MS and TG-FTIR systems are also available commercially. For all EGA systems, the direct coupling of an analytical instrument to a TA system poses significant challenges and the interface has to recognize the different conditions associated with the individual instruments involved and the different time intervals required for sampling. For example, in TA-MS, a TA system usually operates at ambient pressure whereas an MS operates at high vacuum. The necessary coupling interface has to allow for the major pressure gradient between the TA and MS systems while simultaneously transferring a representative sample of the evolved gases from the TA system to the MS system. The most significant problem in this context is to overcome possible condensation of vapors in the interface. Heating of the interface may remedy this problem but may also cause decomposition of the evolved gaseous components (see Figure 1).

TA-FTIR is gaining popularity as a major EGA technique. In contrast to TA-MS, the bulk gas flow from the TA system passes through the FTIR gas cell so the interface does not change the flow rate and pressure of the purge gas – thereby overcoming the possible condensation problems associated with TA-MS. Full-range FTIR spectra can be recorded or spectral sections (windows) can be preselected. Output presentation is in the form of a plot of overall integrated intensity of the IR absorption as a function of temperature. However, the areas of the absorption peaks are dependent on the nature of the species contributing to the absorption; hence, unlike

**Figure 1** Schematic diagram of a TA-MS system showing the capillary inlet and jet separator components. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques and Applications*. Amsterdam: Kluwer.)

typical DTA or DSC peaks, the relative amounts of species cannot be determined. Full or partial IR spectra can be obtained at points on the TA profile to assist the identification of gaseous species evolved at that stage. In cases involving complex mixtures of evolved gases, interfacing a GC system between the TA and FTIR systems refines the overall analysis by effecting online separation of the gaseous components prior to identification.

Fundamentally, EGA systems require powerful software control and data analysis systems, which in addition to controlling the overall hardware and displaying and analyzing output data, may also include libraries of MS or FTIR spectra to assist identification of the gaseous products of a thermal decomposition. However, EGA represents the most comprehensive group of thermoanalytical systems available for the characterization of the thermal behavior of materials. Hence, EGA applications are widespread and diverse. Coordination chemistry has been considerably enhanced by TA studies of a wide range of metal complexes. The emphasis of these studies has been to derive thermal decomposition mechanisms for such metal complexes. Prior to the development of EGA, such mechanisms were suspect, since the volatile decomposition products and the solid intermediates were, in general, not identified directly but characterized indirectly on the basis of mass loss data. This procedure is flawed when multiple gaseous decomposition products and non-stoichiometric intermediates are involved. In this context, even 'simple' inorganic compounds such as copper sulfate pentahydrate are associated with complex thermal decomposition mechanisms. TG-MS is particularly well suited to studies of the thermal decomposition of metal complexes, particularly those of biochemical significance.

TG-DTA-MS has obvious synthetic polymer applications. TA-MS has been applied to study the thermal behavior of homopolymers, copolymers, polymeric blends, composites, residual monomers, solvents, additives, and toxic degradation products. In the latter context, HCl evolution from heated poly(vinyl chloride) materials is readily quantified by TA-MS and such data are of major significance in the design of fire-resistant polymeric materials. Pyrotechnic materials have been studied by TA-MS. A complex sequence of thermal events relates to the decomposition of these materials involving interactions between the nitrocellulose, perchlorate, and metal components with periodic release of carbon dioxide and oxygen. Only by EGA is it possible to rationalize the thermal behavior of such materials. TA-FTIR has also been applied extensively to study the thermal characteristics of synthetic polymers

such as polystyrene. A particular advantage of TA-FTIR in this context is that the output data can be represented as a three-dimensional surface with coordinates absorbance, wavenumber, and temperature. Thus, specific decomposition products, such as water and carbon dioxide, are continuously monitored quantitatively. Various TA-EGA systems have been used to study materials of environmental significance such as contaminated soils, waste (polymeric) products, and packaging materials. Such studies are important in the context of recycling strategies.

Finally, it should be noted that a major disadvantage of TA-EGA systems, particularly TG-MS and TG-FTIR systems, when applied to samples such as synthetic polymers that degrade to produce a variety of complex fragments simultaneously, is the inability to separate the decomposition products prior to analysis. The resulting analytical data are invariably difficult to interpret unambiguously. However, recently, Lever *et al.* have described the use of online sorbent tubes as an alternative to cold traps for condensing the emergent volatile decomposition products. Subsequent analysis of these products is affected by GC-MS by coupling the collection tube to the inlet of a GC-MS system and partially or completely thermally desorbing the decomposition products. A new EGA technique has hence been created – 'evolved gas collection'.

### Introduction

Sample controlled thermal analysis (SCTA) is the generic title for a group of thermal analysis (TA) techniques in which the heating rate is varied so as to produce a constant rate of mass loss. This title has replaced the former title of 'controlled rate thermal analysis' (CRTA). The historical development of 'controlled rate' methodology has been comprehensively reviewed by Reading. SCTA essentially overcomes the problems associated with linear heating rates in conventional TA techniques that can cause significant temperature and pressure gradients in the sample. The judicious use of heating regimes, which are modified in some manner by the reaction rate, can greatly reduce these problems giving enhanced resolution in analytical and characterization investigations. Over the last decade, a family of 'controlled rate' techniques has emerged. The first of these, CRTA, is a method pioneered by Rouquerol and the Pauliks, which involves variation of the sample temperature to maintain a constant reaction rate. This condition essentially ensures pseudoequilibrium conditions are maintained throughout the sample. A constant rate of reaction is maintained by using the measured mass loss or evolved gas pressure as feedback to the furnace temperature controller. The resulting conditions for the analysis correspond to near isothermal and hence 'quasi-isothermal controlled rate thermal analysis' results. Similarly, if the pressure of the evolved gases is maintained constant during a TA experiment, 'quasi-isobaric controlled rate thermal analysis' results. The similarity between these techniques is immediately apparent. Both maintain the reaction rate constant and both control the pressure of the evolved gases in the system. Closely related techniques, which are particularly useful for deriving kinetic information, are those involving a 'temperature jump' or a 'rate jump' – leading to 'stepwise (iso)thermal analysis' (SIA). In the latter, upper and lower limits are set for the reaction rate and when the rate falls below the minimum preset value, the temperature is increased (at a generally fast linear rate) until the reaction rate exceeds the maximum set value. The temperature is then held constant until the reaction rate subsequently falls below the minimum. Further variations of SCTA have been developed by Parkes in which the

reaction rate for gas–solid reactions is controlled by programming the concentration of reactive gas whilst keeping the temperature constant. Also, further variants involve resolution in the temperature and time domains. Time-resolved SCTA techniques are useful in situations where it is necessary to isolate and collect the gaseous products and/or the residual solids of a TA experiment for subsequent identification by other analytical techniques. SCTA has also been developed for the investigation of 'large' samples (1 g) – thereby characterizing SCTA as a 'preparative' technique. A further variant within the SCTA family is 'Hi-Res' TG<sup>TM</sup> or 'Dynamic Rate' TG, in which the heating rate is reduced when the system crosses the upper threshold set for the reaction rate. The changes in heating and cooling rates are controlled by adjustment of the values of two numerical parameters – 'resolution' and 'sensitivity'. Temperature modulated SCTA is a further recent development. Since SCTA essentially eliminates sample 'self-heating' and inhomogeneous reaction within a sample, the resolution of SCTA is generally greater than that associated with conventional TA techniques.

### The Basic Principles of SCTA Techniques

It has already been stated that SCTA envelopes the original CRTA techniques. Essentially, there are two forms of CRTA – the quasi-isothermal/quasi-isobaric methods (Paulik) and the constant rate method (Rouquerol). The Paulik method is based on thermogravimetry (TG) and is known as 'Q-TG'. It depends on a control system that maintains a constant rate of mass loss and the measured parameter is temperature as a function of time. CRTA relies on using a transducer to monitor the pressure of evolved gas in a continuously evacuated chamber. The sample is heated in such a way as to maintain the monitored gas pressure constant. Since the pressure is maintained constant, the rate of gas pump-off is maintained constant and thus the rate of mass loss (when a single gas is evolved) is also maintained constant. Hence, CRTA is effectively vacuum thermogravimetry. The similarity between the Paulik and Rouquerol techniques is immediately apparent. Both maintain the reaction rate constant and both control the pressure of the evolved species in the reaction environment. Hence, the differences in the techniques are purely semantic. These techniques allow a precise

control of the uniformity of the reaction environment, which is effected by controlling the evolved gas pressure and the temperature and pressure gradients within the sample. Further, these techniques avoid artifacts that arise from a nonuniform sample environment such as artificial broadening of the temperature interval over which a reaction occurs and hence controlled rate techniques are ideal for kinetic studies. The ability of controlled rate techniques to resolve multiple thermal events is generally superior to conventional TA methods and is hence a further advantage.

Over the last decade, it has been internationally accepted that the generic title for TA techniques whereby the heating rate is controlled using a feedback loop as some function of the rate of reaction or the chemical or physical process under study should be sample controlled thermal analysis (SCTA) and this title now embraces Q-TG, CRTA, SIA, and dynamic rate thermal analysis.

Parkes *et al.* have described further variations of SCTA involving resolution in the time and temperature domains. In TA, resolution is related to the extent to which adjacent or partially overlapping thermal events are separated. In a conventional TA experiment, involving linear sample heating, the resolution in either the time or temperature domain is essentially the same and thus the TA profiles as related to either temperature or time are similar. However, this criterion is not the same for SCTA experiments in which the relationship between time and temperature is always nonlinear when a reaction is occurring. Consequently, SCTA curves displayed as a function of time are markedly different from those displayed as a function of temperature. Overall resolution is markedly enhanced with both types of 'resolved SCTA' techniques.

Conventionally, high resolution in TA is achieved by using low linear heating rates and small sample masses so that the sample reacts under near equilibrium conditions. However, these conditions lead to long experimental times and generally to low sensitivity. CRTA and SIA are basically similar, as essentially heating is slow through thermal events and fast between them. Such a heating regime provides all the benefits of a very low linear heating rate but with a reduced time penalty as compared to a TA experiment using the same linear heating rate, since the heating rate is faster during periods corresponding to no thermal events. Such heating strategies cause processes to occur over a very narrow temperature range (zero temperature range in the case of SIA) in both cases and leads to an increase in resolution in the temperature domain. However, one severe limitation of both SIA and CRTA is long experimental

times as compared to the time taken to complete a conventional TA experiment using a linear heating rate. Parkes *et al.* have described a temperature-resolved SCTA technique using 'proportional heating' (PH) in which the heating rate is proportional to a function of the reaction rate. Essentially, PH offers maximum temperature resolution within a minimum time frame. PH smoothly varies the heating rate between preset maximum and minimum values so as to provide the optimum balance between resolution (which is to be maximized) in the temperature domain and experimental time (which is to be minimized). The operation of the PH method depends on four main parameters: maximum and minimum heating rates, a 'target' reaction rate, and a function relating heating rate to reaction rate. When the reaction rate is zero, the heating rate is set to its maximum value and when the reaction rate is at, or above the preset target level, the heating rate is set to its minimum value. Between these limits, the heating rate is related to the reaction rate by one of several possible functions.

Temperature-resolved SCTA techniques operate by controlling the sample temperature as some function of the difference between the measured reaction rate and a preset 'target' rate. However, it is difficult to set a single level that is equally appropriate for complex systems that are associated with thermal events of different magnitudes. The basic principle of time-resolved SCTA is focused on maintaining a linear heating rate throughout a thermal event and reducing it to a very low level between two consecutive thermal events. However, a proviso applies – that the consecutive thermal events are well resolved. The initial linear heating rate imparts enhanced sensitivity since the process is forced to occur over a short time interval. Between the two thermal events, the very low heating rate increases the time between them and thus enhances resolution in the time domain. Thus, time-resolved SCTA is opposite in principle to temperature-resolved SCTA. Parkes *et al.* have described a time-resolved SCTA technique – termed peak-slope heating (PSH) in which the heating rate becomes zero when the rate of change of the reaction rate changes from positive to negative – immediately following a peak maximum. Conversely, the heating rate is increased as soon as the end of a thermal event is detected. PSH has a major advantage over temperature-resolved SCTA techniques in that the change in heating rate takes place at the same relative point on the peak, irrespective of its absolute magnitude. This eliminates the need to select a target reaction rate prior to the start of each experiment. For cases involving partial overlap of two thermal events, a more complex form of time-resolved SCTA

applies – known as peak-resolved heating (PRH), which relies on switching the heating rate at the point corresponding to the greatest acceleration of the reaction rate.

Summarizing, SCTA techniques are associated with six types of sample heating regimes: linear heating (LH) – the sample is subjected to a predetermined heating regime, including isothermal and cooling regimes; constant rate (CR) – the rate of a thermal event is made to proceed at a constant rate by variation of the sample temperature; stepwise isothermal – the sample is either heated or held isothermally so as to maintain the reaction rate between two predetermined thresholds; PH – the heating rate of the sample is directly proportional to its reaction rate (rapid heating of the sample occurs during thermal events and slow heating of the sample occurs between thermal events); PSH – the heating regime of the sample is switched from ‘heating’ to ‘isothermal’ at maximum reaction rate (slow heating of the sample occurs during thermal events and rapid heating of the sample occurs between thermal events). PSH is opposite to PH; and PRH – which is a more advanced form of PSH in which switching of sample heating corresponds to the point of maximum acceleration of reaction rate.

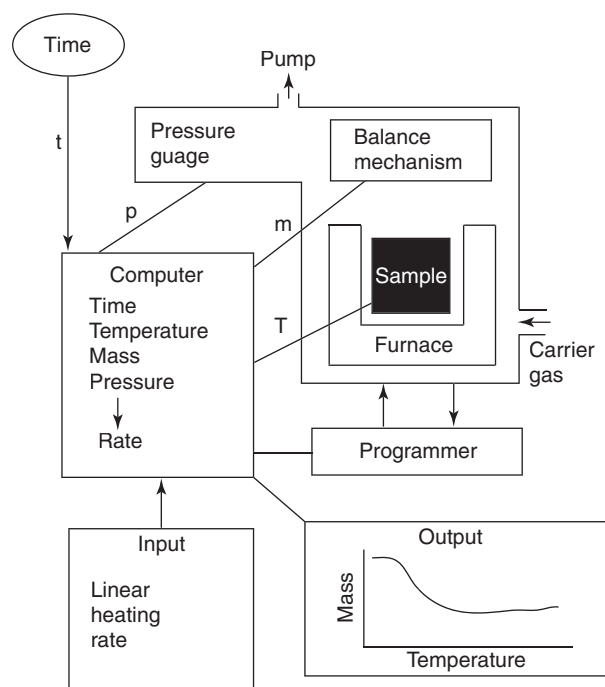

Temperature- and time-resolved SCTA techniques have major advantages over conventional TA techniques. Temperature-resolved SCTA can give information on reaction mechanisms that are not apparent from corresponding linear heating experiments. Temperature-resolved SCTA is also particularly advantageous for the *in situ* preparation of porous or finely divided solids by thermal decomposition and for the study of catalytic materials. Time-resolved SCTA is particularly useful in conjunction with an evolved gas analysis system whereby time resolution of evolved gases leads to their unambiguous identification.

The basic principles of SCTA have recently been incorporated into a commercial TG system developed by TA Instruments (USA) and known as ‘Hi-Res’ TG<sup>TM</sup> – an acronym for ‘High-Resolution TG’. This system allows for four heating regimes – a conventional constant heating rate; a stepwise isothermal mode, whereby the sample is heated until a reaction is detected and then held constant until the reaction is complete; a constant reaction rate, whereby heating of the sample is controlled to achieve a constant rate of mass change; and ‘dynamic rate TG’, which varies the heating rate smoothly and continuously in response to the rate of sample decomposition, so that the resolution of mass change is maximized. In addition, many ‘homemade’ SCTA systems have been developed, as described in the next section.

## SCTA Instrumentation

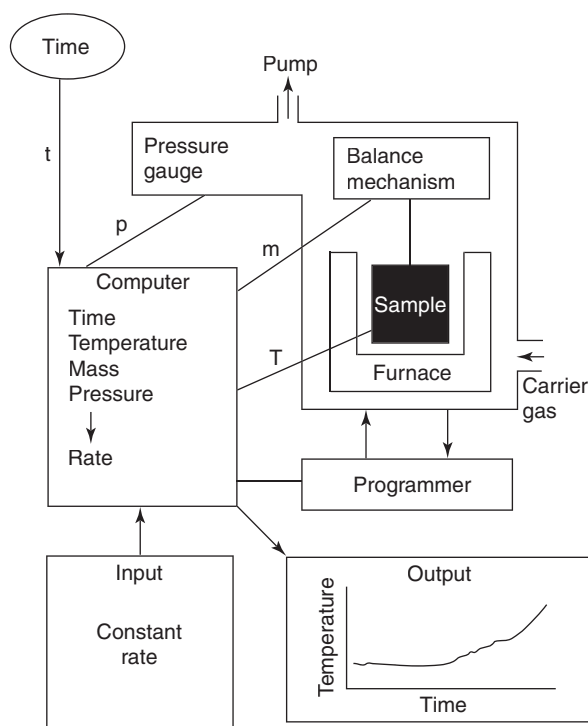

The essential difference between conventional TA and SCTA is the input to the control system. In conventional TA, a linear (sample) heating rate is imposed, whereas in SCTA the heating rate is related directly to the reaction rate. Figures 1 and 2 schematically show the key features of conventional TG and SCTG and define the ‘input’ condition for each system.

It is well-known that sensitivity and resolution in conventional TA are achieved by small sample sizes and rapid heating rates. SCTA offers unique possibilities for ‘preparative scale TA’ whilst maintaining high levels of sensitivity and resolution. The University of Huddersfield Centre for Thermal Studies has recently developed a ‘preparative scale TG’ system, which incorporates the principles of SCTA – specifically, the PH facility. The focus of the SCTG system is a five-decimal place top-pan balance (Stanton-Model BP211D) and a high-temperature water-cooled furnace (Stanton Redcroft), located above the balance and allowing operation to 1000°C (Figure 3). The sample is contained in a silica or platinum crucible and sits on top of a rise rod connected directly to the balance pan. Samples in excess of 1 g can be investigated, but routinely samples of 500 mg are usually involved. Grinding of powdered samples to mesh size 150–250 µm is advantageous. The sample temperature is monitored by a thermocouple located

**Figure 1** Schematic of a TG system. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques & Application*. Amsterdam: Kluwer. )

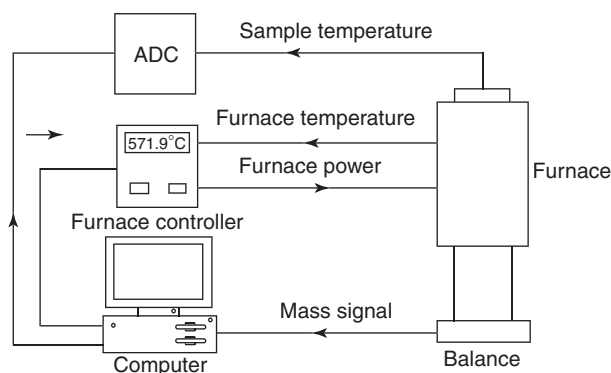

**Figure 2** Schematic of an SCTA system. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques & Application*. Amsterdam: Kluwer.)

centrally within the furnace tube. Radiation shields attached to the thermocouple reduce convection currents within the sample region. A gas diffusion chamber, situated between the balance and the furnace, permits experiments to be carried out in an upward flow of gas at a constant flow rate via continuously pumping the system. Although the overall system is not sealed, this net gas flow prevents air entering the system and results from the differential flow rates at the inlet and at the outlet, as measured by individual flow meters. Volatile decomposition products can be trapped using a combination of filters and activated charcoal and liquid nitrogen traps.

A block diagram of the data acquisition and control systems is shown in Figure 4, which are a development of those used for sample controlled studies based on evolved gas analysis techniques. The temperature of the furnace is continuously varied by a temperature controller and the output from the balance and from the sample temperature thermocouple are logged by a Pentium computer, fitted with a 16-bit dynamic range data acquisition board. The signals are processed via a program derived using a combination of Virtual Basic and C<sup>++</sup> and the derivative of the TG curve is used to control the heating program via the temperature controller. Several SCTA modes are available with this system – including

**Figure 3** Schematic of an SCTG system. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

**Figure 4** SCTG control system. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

linear heating TG and PH TG. In addition, the control software has a 'stop-mass' facility, by which 'products' can be produced at any preselected degree of reaction – thereby conforming to the 'preparative' aspect of the SCTG system. Modifications to the control system give rise to time-resolved SCTA

incorporating peak slope heating and dynamic rate modes. This 'in-house' construction is thus a very versatile SCTA system that incorporates the principal advantages of 'sample controlled' methodology.

## SCTA Applications

Major developments in SCTA together with diverse applications of these techniques have been made by the University of Huddersfield – Centre for Thermal Studies and the Centre for Applied Catalysis – and the following discussion represents a summary of the recent achievements of these research centers in SCTA. Specifically, these centers have been responsible for the development of temperature- and time-resolved SCTA and these techniques have been systematically applied to study the thermal behavior of coals and catalytic materials with consequential major advances in these fields.

The principal advantage of SCTA over conventional TA techniques is that in the former, thermal events can be studied under controlled conditions. A simple example of 'controlled decomposition' is the thermal decomposition of sodium bicarbonate and SCTG and TG curves for this process are shown in Figure 5. The most striking feature of the (proportional heating) SCTG curve is controlled decomposition over a narrow temperature range. The corresponding TG curves show a reduction of the decomposition temperature range with decreasing heating rate but the SCTG decomposition temperature range corresponds to zero heating rate of the sample, and hence via SCTA, the most realistic thermal decomposition temperature ranges are obtained. This feature is of particular significance

for samples that violently decompose or ignite such as pyrotechnics and coals. The primary advantage of the sample controlled approach in reducing both temperature and concentration gradients in a sample is illustrated by the oxidation of a Drayton coal sample (Figure 6). Even at a 500 mg sample level, a controlled oxidation is apparent and ignition is avoided. In conventional TA using the same conditions, self-heating of the sample leads to ignition and hence a loss of meaningful data after ignition, coupled with 'apparent' decomposition temperature ranges. Similarly, the controlled oxidation of four different coals is shown in Figure 7. Although the SCTG profiles are similar in character and reveal controlled oxidation, the subtle differences in oxidation behavior of these coals are revealed. Such differences are not readily deciphered from TG curves

**Figure 7** SCTG curves for the oxidation of different coals. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

since the dominating feature is ignition that masks the intermediate thermal events. Coal pyrolysis can also be studied by SCTA in a nitrogen atmosphere. The PH SCTG curve for the pyrolysis of a sample of

Illinois coal is shown in **Figure 8**. Initial pyrolysis occurs over a relatively narrow temperature range and the slow nature of the latter stages of pyrolysis is indicated by the temperature program returning to

**Figure 8** SCTG curve for the pyrolysis of Illinois coal. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

**Figure 9** SCTG curve for the oxidation of Drayton coal char. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

**Figure 10** SCTG curve for the oxidation of zirconium powder. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

**Figure 11** SC-thermomagnetometry curve for 'ICTAC Nickel'. (Reproduced with permission from Professor Edward L. Charsley, Centre for Thermal Studies, The University of Huddersfield, Huddersfield, UK.)

**Figure 12** LH (A) and PH (B) curves for the dehydration of copper sulfate pentahydrate. (Reproduced with permission from Parkes GMB, Barnes PA, and Charsley EL (1999) *Analytical Chemistry* 71: 2482–2487.)

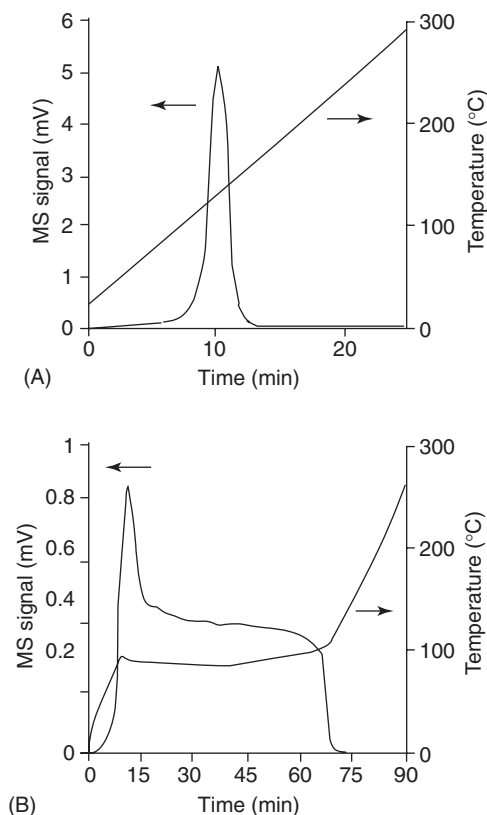

maximum heating rate. The 'stop-mass' facility of an SCTG system provides 'preparative opportunities' and in the context of coal pyrolysis, chars can be produced at any stage of the pyrolysis process that can subsequently be characterized by other analytical techniques. Further, the oxidation of such chars can be monitored by SCTG as shown in Figure 9 for a Drayton coal char. Prior to the development of SCTA, coal char TA was beset with controversy due to the indecisive nature of the derived data.

The high reactivity of finely divided zirconium powder toward aerial oxidation makes conventional TA studies difficult to perform under controlled conditions. Figure 10 shows an SCTG curve for a 10 mg sample of zirconium powder, which in a TG-DTA experiment under similar conditions but using a linear heating rate shows ignition at  $\sim 410^\circ\text{C}$ . However, it is apparent that under PH SCTG conditions, a smooth oxidation reaction process results, which is 50% complete below  $400^\circ\text{C}$ . These types of studies are most suitable for pyrotechnic mixtures, since reliable ignition data are generated.

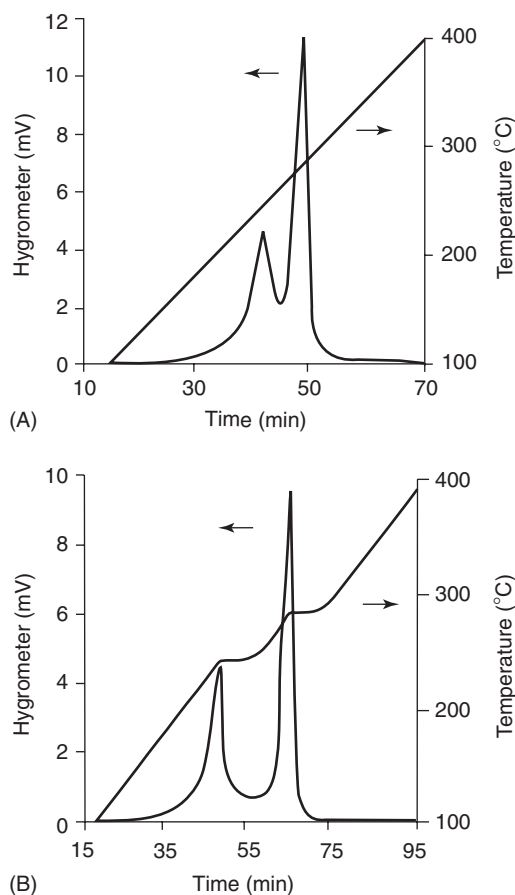

The possibility of performing sample controlled thermomagnetometry is illustrated by an SCTM

experiment on ICTAC nickel, with a magnet placed above the thermobalance furnace (Figure 11). During the heating program, the sample oscillates between the magnetized and unmagnetized states. If a zero cooling rate is applied, this transition can be made to take place over a narrow temperature range thereby characterizing the magnetic property of the metal.

The scope of temperature- and time-resolved SCTA has been revealed by Parkes *et al.* via studies of the decomposition of inorganic salts. Temperature-resolved SCTA is particularly useful for resolving the dehydration characteristics of copper sulfate pentahydrate. A typical TG profile for this salt is shown in Figure 12 and compared with a PH SCTG profile over the same temperature range. The typical 2:2:1 water loss is shown in both profiles but the resolution of these peaks is superior in the SCTG profile. Further, the latter shows how the heating rate is reduced through each dehydration peak and increased between each peak, which is the defining feature of temperature-resolved SCTA. Further,

**Figure 13** LH (A) and PH (B) curves for the decomposition of ammonium hydrogencarbonate. (Reproduced with permission from Parkes GMB, Barnes PA, and Charsley EL (1999) *Analytical Chemistry* 71: 2482–2487.)

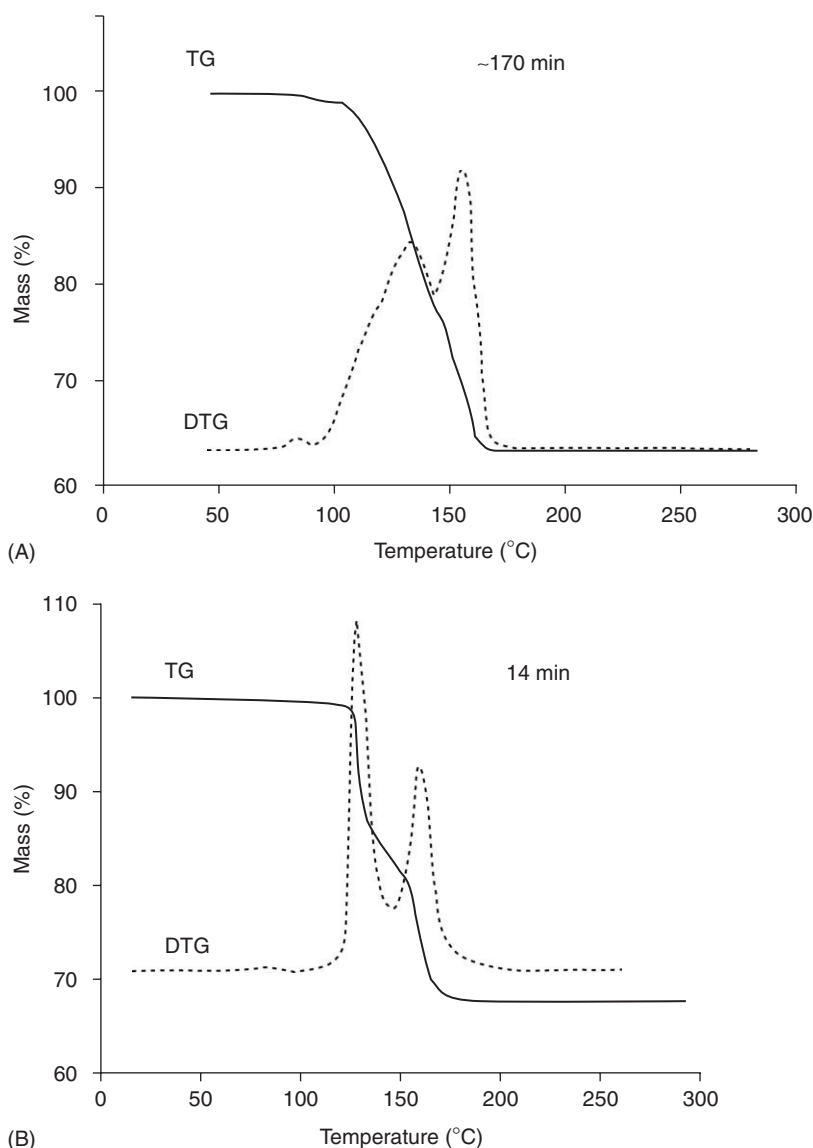

**Figure 14** LH (A) and PH (B) curves for a 1:2 mixture of copper and zinc hydroxycarbonates. (Reproduced with permission from Parkes GMB, Barnes PA, and Charsley EL (1999) *Analytical Chemistry* 71: 2482–2487.)

temperature-resolved SCTA can be used in mechanistic studies of complex reactions. The decomposition of ammonium hydrogencarbonate is associated with the co-evolution of ammonia, water, and carbon dioxide. PH SCTA in conjunction with mass spectrometry was applied to study this decomposition process and linear heating and PH TA curves are shown in Figure 13. A single decomposition peak, centered at 125°C is apparent from the linear heating profile, whereas the PH profile shows the presence of a nucleation stage prior to decomposition thereby providing mechanistic indications of the decomposition mode.

An application of the time-resolved SCTA technique is shown in Figure 14 relating to LH and PSH

of a 1:2 mixture of copper hydroxycarbonate and zinc hydroxycarbonate. Decomposition of this mixture yields both carbon dioxide and water and the latter was monitored using a hygrometer. The principal feature of time-resolved SCTA is shown by the PSH profile. It is apparent that the switch to zero heating rate on the falling edge of each peak is rapid, whereas the increase in heating rate as the first decomposition approaches completion is slower. Also, the switching point between heating and nonheating is at the same relative point on each peak despite their difference in size. The enhanced resolution of the decomposition peaks without distortion of shape is clearly apparent from the PSH profile and this feature is indicative of the ability of PSH

**Figure 15** TG (A) and 'Hi-Res' TG<sup>TM</sup> (dynamic rate) (B) curves for a sodium/potassium carbonate mixture. (Reproduced with permission from Haines PJ (ed.) *Principles of Thermal Analysis and Calorimetry* (2002). Cambridge: Royal Society of Chemistry.)

to time-resolve gaseous decomposition products for 'online' evolved gas analysis.

It should, however, be noted that although both PH SCTA and peak-resolved SCTA provide enhanced resolution in the temperature and time domains, respectively, both of these modes are typically associated with increased experimental times compared to those of conventional TA experiments. This feature at present eliminates SCTA as an analytical technique for the rapid characterization of materials and in quality control applications. However, these techniques offer many other advantages, most notably in providing mechanistic and kinetic information on thermal decomposition behavior of materials.

TA Instruments (USA) have recently produced a commercial SCTA system – known as 'Hi-Res' TG<sup>TM</sup> or 'Dynamic Rate' TG<sup>TM</sup>. The basic principle of this system is that there is a marked decrease in heating rate when the system crosses a preset upper reaction rate threshold. The changes in heating or cooling rates are controlled by adjustment of the values of two numerical parameters, referred to as 'resolution' and 'sensitivity'. 'Dynamic Rate' TG varies the heating rate smoothly and continuously in response to the rate of sample decomposition so that the resolution of the mass change is maximized. This mode allows rapid heating in regions where no transitions occur and proportionally slow heating during reactions. The latter form of 'Hi-Res' TG<sup>TM</sup> is illustrated by conventional TG (linear heating) and dynamic rate TG profiles for a sodium/potassium hydrogencarbonate mixture (**Figure 15**). It is apparent from the latter profile that enhanced resolution of the decomposition peaks is achieved in a time frame of less than 10% of the conventional TA experiment.

It is apparent that the future of SCTA is likely to be focused on maximizing the resolution/experiment time ratio inherent in these techniques. PH SCTA is a refinement of the Rouquerol CRTA technique but the associated long experimental times present an operational drawback. PSH SCTA, which heats quickly into thermal events but slowly between them, gives enhanced resolution in the time domain whilst maintaining sensitivity levels comparable to conventional TA techniques, but again at the expense of increased experimental times. The TA Instruments 'Dynamic Rate' TG<sup>TM</sup> appears to address both of these parameters and hence has much potential as a 'high resolution/rapid TA system'.

Finally, it is well recognized that TA can be applied in the complex domain of reaction kinetics. Since 'reaction rate' is the key concept on which SCTA techniques are based, these techniques collectively are becoming increasingly applied to study reaction mechanisms and to derive kinetic data for thermal decomposition processes of a wide range of materials. It is this type of application that will characterize SCTA as a dominant group of techniques for studying reaction energetics.

### Introduction

'Less common thermal analysis (TA) techniques' encompass those TA techniques that monitor 'less obvious' properties of a sample as a function of temperature and hence these are specialized techniques that require specialized instrumentation. 'Less common techniques' are not synonymous with 'less used techniques' but relate to a field of TA that is less well developed as a result of being highly specialized. Some of the 'less common TA techniques' are 'standalone techniques' and are associated with International Confederation for Thermal Analysis and Calorimetry (ICTAC) approved definitions. Others in this group are variants of 'more common' TA techniques and do not have ICTAC approved definitions but, nonetheless, are viable TA techniques. In the former category, thermal techniques such as emanation thermal analysis (ETA), thermoelectrometry, and thermosonimetry (TS) are noteworthy. In the latter category, a range of techniques has emerged that focus on the method of heating of the sample. Techniques such as 'microwave thermal analysis' (MWTa) and 'programmed probe analysis' fit into this category. The former technique involves microwave heating of the sample and the latter technique is effectively an evolved gas analysis (EGA) technique and involves the rapid heating of the sample by the probe of a mass spectrometer. Techniques currently in the 'less common' category, such as micro-thermal analysis ( $\mu$ -TA), are becoming 'more common' as the major advantages of such techniques become increasingly self-evident. Also, with a progressive blurring of the edges of TA and a progressive inclusion of 'calorimetry' into the thermal studies domain, a wide range of 'special purpose calorimeters' has emerged which have 'less common' application, but which have very significant impact in terms of advancing the overall emphasis and application of TA techniques. The 'less common TA techniques' group provides a further insight into the diversity, complexity, authenticity, and superiority of this category of analytical techniques, which collectively have revolutionized studies of materials over several decades and promise analytical opportunities in support of the nanotechnological age.

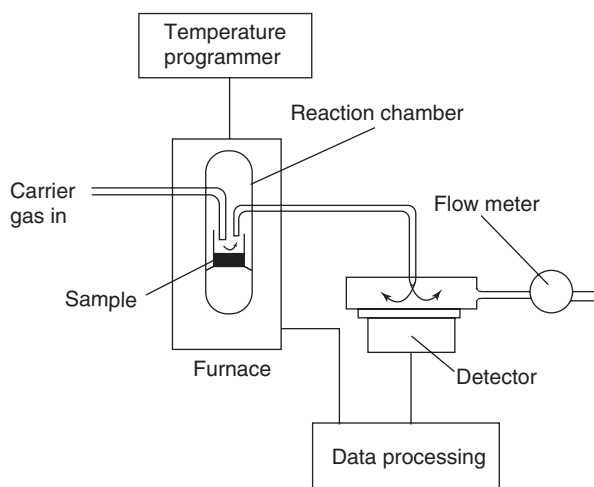

### Selected 'Less Common' TA Techniques

Emanation TA involves the measurement of the release of inert (usually radioactive) gas from a solid sample as a function of temperature. The rate of such gas release is essentially an indication of the changes taking place in the sample and a comparison of ETA data with those of other TA techniques, particularly thermogravimetry (TG) and EGA, provides information on the microstructure of the sample material. However, most of the solid samples studied by EGA are 'spiked' with 'inert gas', which is trapped at lattice imperfections and the latter also provide diffusion pathways for adsorbed gases. It is this pre-spiking procedure that characterizes ETA as a less-common TA technique. Several methodologies are available to effect the required 'spiking'. These are essentially divided into two groups: techniques for introducing the parent nuclide of an inert gas and techniques for introducing the inert gas itself. The former group of spiking techniques is preferable since labeling the sample with a parent nuclide gives an enhanced timeframe over which the inert gas can be desorbed from the sample, since it is formed continuously *in situ*. With the second group of techniques, the absorbed inert gas may be lost from the sample over the timeframe of a single run.

ETA is usually carried out in conjunction with other TA techniques, most notably differential thermal analysis (DTA) and EGA. In this context, ETA can be considered as a coupled TA technique. Carrier gas, at a constant flow rate, is used to carry released gas from the sample to appropriate detectors – usually radioactive counting devices. In the case of desorbed radon, a scintillation counter is used, whereas Geiger counters are used for krypton, xenon, and argon. A typical ETA system is shown schematically in **Figure 1**. An ETA curve is a plot of 'emanating power'  $E$  as a function of time and the  $E$ /time relationship has been developed and defined by Balek.

A major difficulty of ETA is that preparation and handling of samples requires sophisticated radiochemical facilities coupled with the associated precautions. However, the net amounts of radioactive gas incorporated into samples are so small that the evolved gas, after dilution with the carrier, does not pose a significant hazard.

One of the major applications of ETA is the characterization of powders. Emanating power is related directly to surface area and hence changes in grain

**Figure 1** Schematic of an ETA system. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques and Applications*. Amsterdam: Kluwer.)

size and the occurrence of sintering during heating can readily be detected. Kinetic parameters related to sintering can also be derived. Solid-state phase changes can also be manifested as changes in emanating power. In this context, ETA data can be correlated with DTA, differential scanning calorimetry (DSC), and thermo-mechanical analysis (TMA) data related to phase changes of solid-state materials. ETA has also been applied to study solid–gas reactions such as the oxidation of metals and the reduction of metal oxides. In this respect, ETA data are useful for studying surface phenomena and hence ETA has potential for future applications in the study of corrosion and catalytic processes. Solid–solid reactions, such as spinel formation between zinc oxide and iron(III) oxide can be studied by ETA by labeling ZnO with a radioactive thorium isotope. It is apparent that the two reactant oxides interact in a series of stages involving an initial surface diffusion process and a final volume (bulk) diffusion process. These processes are not readily detected by other TA techniques such as DTA or TMA curves but are clearly shown by increased emanation with clear definitions of the corresponding temperature ranges. The reactivities of oxides can readily be determined by ETA in terms of the mutual reactivities toward spinel formation.

TS involves the measurement of the sound intensity emitted by a sample as a function of temperature. Sound emission originates from the release of thermal stresses in the sample, such as movement of dislocations, generation and propagation of cracks, nucleation of new phases, relaxation processes, and discontinuous changes in physical properties. For example, at a glass transition temperature, a discontinuous change in free volume generates elastic waves

that cause an acoustic effect. Such stress–relief processes are not usually detectable by conventional TA techniques, due to the low associated energy; hence, TS has many unique applications such as the detection of radiation damage, crystal defect content, and degree of annealing of polymeric samples. It is also complimentary to TMA for the detection of mechanical effects associated with melting, dehydration, decomposition, and for studying a range of solid-state phase changes.

TS is usually carried out in conjunction with DTA and sound energy is emitted as mechanical vibrations prior to and during thermal events associated with the sample over defined temperature ranges. Such sonic activity is detected by a specially adapted stethoscope. The mechanical waves are converted to electrical signals by conventional piezoelectric transducers. The stethoscope is constructed of fused silica for operation to 1000°C – for higher operating temperatures, ceramics or noble metals can be used. The sample is contained in the DTA sample head, which in turn acts as an acoustic transformer and is connected via a transmitting rod to a piezoelectric sensor, fixed on a recoil foundation and a seismic mount to prevent interference from external noise. A schematic diagram of a TS–DTA system is shown in **Figure 2**. Several special aspects of the instrumentation enhance sensitivity. The waveguide system transmits the acoustic emissions from the heated sample to the transducer at ambient temperature so as to nullify the effect of temperature on the transducer and the sample temperature thermocouple is located close to but not in contact with the sample since insertion of the sensor in the sample can cause mechanical damping effects that directly affect acoustic activity.

The output of a TS experiment consists of a rapid cascade of decaying signals that may be recorded in several ways; as the number of signals of peak amplitude greater than a set threshold value in a given time; the time for which the signal amplitude exceeds the threshold value; the time frequency that signals pass through a chosen voltage level in a positive direction; and the root-mean-square amplitude level (energy or as a set of frequencies). In general, interpretation of TS data is complex. Attempts have been made to relate frequency distributions to processes (thermal events) occurring in the sample. In the simplest interpretation, frequency distributions can be used as ‘fingerprints’ of sample origin. Superficial interpretation of TS data is also possible in that ‘bubble release’ is associated with low frequencies and crystal fracture or distortion is associated with high frequencies. In general, TS, with suitable refinements, is a powerful technique for rationalizing a wide variety of solid-state phenomena. For example, TS has been

**Figure 2** Schematic of a TS-DTA system. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques and Applications*. Amsterdam: Kluwer.)

applied to study the dehydroxylation behavior of kaolins, which show two regions of acoustic activity. The low-temperature region corresponds to dehydroxylation and the high-temperature region corresponds to recrystallization to metakaolinite. TS is also useful for identification of 'pretransition' activity in a sample. The TS curve of potassium perchlorate shows acoustic activity prior to the transition temperature of 299°C, which corresponds to the release of included fluid. Similarly, the TS curve of potassium sulfate shows acoustic activity prior to the transition temperature of 582°C, which corresponds to the formation of microcracks in the sample structure. A DTA study of potassium perchlorate shows melting at 340°C and two successive exotherms due to decomposition to potassium chloride over the range 540–610°C. Simultaneous DTA-TS shows a total of four acoustic events for potassium chlorate. The first two TS peaks are associated with 'postmelting' activity directly related to the formation and evolution of gas bubbles in the melt.

A complementary technique – thermoacoustimetry – involves the measurement of the characteristics of imposed acoustic waves after passing through a sample as a function of temperature. The instrumentation for thermoacoustimetry is complex and is shown

**Figure 3** Schematic of a thermoacoustimetry system. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques and Applications*. Amsterdam: Kluwer.)

schematically in Figure 3. In one version of a thermoacoustimetry system, the sample is contained between a pair of lithium niobate transducers under an applied pressure of 300 kPa. One transducer induces the incident acoustic signal and the other detects the transmitted signal. Thermal expansion of the sample during the heating program is monitored continuously by a linear variable differential transducer. Atmosphere control of the sample environment is also possible. The incident signal is generated by a pulse generator. The transmitted signal received by the second transducer is inverted and amplified and an attenuated version of the driving pulse is added to this output signal. This summation procedure enables detection of the both compressional (P) and shear (S) waves. The velocities of the P and S waves and hence the corresponding elastic moduli are thence computed over temperature intervals and the final output is a plot of velocity or modulus versus temperature. The instrument is calibrated by an aluminum standard for which the P and S wave velocities are accurately known.

Thermoacoustimetry has been applied to differentiate between different grades of oil shales. Both the P and S wave velocities decrease with increasing temperature and with increasing organic content. Discontinuities and peaks in the P wave velocity/temperature plots relate directly to loss of included water and decomposition of some hydrocarbon fractions. Thermoacoustimetry, in conjunction with DTA, has been applied to examine the characteristics of

synthetic fibers. Generally, there are two significant increases in signal output, the first at the glass transition and the second prior to melting. The glass fiber form shows no thermal activity in this temperature range.

It is apparent that both these 'acoustic' TA techniques examine the 'fine-structure' associated with solid-state thermal events. Thus, these techniques are particularly suitable for a detailed TA of 'surface' and 'bulk' properties of solids, together with lattice imperfections. Microimpurities and the interactions of these with the host are also able to be evaluated by these specialized techniques. In particular, water inclusions in a host lattice can, in principle, be characterized in terms of the degree of bonding involved and the dehydration characteristics of the material under examination can be determined. These techniques have major analytical potential in materials science, mainly in terms of providing refinements to the traditional understanding of solid-state physical phenomena.

Thermoelectrometry or thermoelectrical analysis (TEA) is the generic title for a group of techniques involving the measurement of electrical properties of a sample as a function of temperature. The electrical properties commonly measured in TEA are conductance, capacitance, and dielectric properties. The most prominent technique in TEA is dielectric thermal analysis (DETA), which involves measurements of both the capacitance and the conductance of the sample as functions of time, temperature, and frequency. The former is the ability of the sample to store charge whilst the latter is a measure of its ability to transfer charge. Four parameters are associated with DETA: the permittivity, the loss factor, the dissipation factor, and the ionic conductivity. These parameters provide information related to molecular motion within the sample and as for most TA

techniques, it is the variation in these parameters during thermal events that is of primary interest rather than their absolute values. Hence, in DETA, the sample is subjected to an oscillating sinusoidal electric field and the applied voltage produces a polarization within the sample and causes a current to flow which in turn leads the electric field by a phase difference ( $\partial$ ). DETA is somewhat related to the thermomechanical techniques, in that the net current flow is similar in nature to the deformation brought about by applied mechanical stress and represents a measure of the freedom of charge carriers in the sample to respond to the applied field. Also, DETA is able to differentiate between different types of 'charge carriers' in the sample. Dipoles will attempt to orientate with the applied electric field, whereas ions, which are often present as impurities, will migrate toward the electrode of opposite polarity. DETA is therefore of significance as an analytical technique for 'quality control' applications.

A schematic diagram of a typical DETA system is shown in **Figure 4**. The sample is presented as a thin film, typically no more than 1–2 mm thick, sandwiched between two parallel plates so as to form a simple electrical capacitor. A grounded electrode surrounding one plate, known as a 'guard ring', is incorporated so as to nullify stray electric fields. The sample temperature sensor is a thermocouple or a platinum resistance thermometer, which is placed in contact with one of the plates. The sample is connected to the inverting input of an operational amplifier, configured as a current-to-voltage converter with capacitive feedback. The measured phase shift of this network can be related to the dielectric properties of the sample. There are two operational modes in DETA: using a continuous range of frequencies (50 Hz to 1 MHz) at preselected temperatures, or over a continuous range of temperatures at

**Figure 4** Schematic of a DETA system. (Reproduced with permission from Brown ME (2001) *Introduction to Thermal Analysis – Techniques and Applications*. Amsterdam: Kluwer.)

selected frequencies. The latter is the more common operating mode for the study of phase transitions and chemical reactions in a sample. Temperature calibration in DETA is effected by measuring the melting transition of a low-molar-mass organic powdered material, such as benzoic acid.

DETA is a highly specialized TA technique but is particularly useful for detecting polar impurities in nonpolar materials such as commercial polymers. Thus, DETA and the thermoelectrometric techniques in general occupy a specialized niche in the TA application field in the context of addressing a specific problem. For example, the TA of thin films can be problematic due to the very small amount of material involved. The glass transition behavior of adhesives affects the tack and bonding behavior and the analysis of adhesive films by DSC is difficult unless the film is removed from any backing support material. DSC analysis of such films is usually undertaken by swelling the adhesive in a suitable solvent and scraping it off the supporting substrate. However, the intrinsic properties of the adhesive may change in this process, even if the sample is subsequently dried to remove residual solvent. DETA, however, is ideally suited to the direct analysis of thin films, and so long as the support does not undergo any thermal transitions in the region of interest, DETA can measure the thermal properties of the adhesive *in situ* without any sample pretreatment.

DETA essentially involves monitoring the viscosity of a system via its ability to store and transport electrical charge. Changes in the degree of alignment of dipoles together with the ion mobility provide information relating to physical transitions in the sample and to changes in properties such as viscosity, rigidity, reaction rate, and cure state. DETA is particularly useful for characterizing the cure process of polymers. Polymers contain ionic impurities and the application of a voltage between two electrodes creates an electric field that forces such ions to migrate to the oppositely charged electrode. However, the conductivity of the material depends on the magnitude of the viscous drag experienced by these ionic impurities. Ions moving through polymerized (rubbery) materials have low mobility and conductivity corresponding to the high viscosity of the medium. Since the degree of cure in synthetic polymers is proportional to the degree of polymer cross-linking, the cure process can be monitored by monitoring the conductivity of the material throughout the entire curing process and DETA is able, more than any other TA technique, to determine the 'cure endpoint'.

DETA can also be used very effectively for the *in situ* monitoring of the ultraviolet (UV) degradation of adhesives such as tinted self-adhesive plastic films

used to screen out direct sunlight from penetrating buildings and vehicles. Attached to the window glass, the adhesive directly receives solar radiation and must be stabilized against photodegradation by a suitable blend of polymer and stabilizer. A modified form of DETA, in which the sample temperature sensor is an interdigitized single surface dielectric sensor, can be used to study such systems. The window film samples are mounted on glass plates for accelerated aging. A small hole is cut into the plastic film and the interdigitized sensor is applied to the exposed surface of the adhesive after freezing the plate to aid the removal of the backing. Measurements of the dielectric and permittivity factors are made at ambient temperature as a function of frequency. Such measurements correlate UV aging of the film with changes in dielectric behavior of the adhesive and, hence, optimized polymer/stabilizer formulations can be identified.
